

“Production and assessment of novel
unspecific peroxygenases through modular
yeast secretion systems”

Dissertation

zur Erlangung des Doktorgrades der Naturwissenschaften
(Dr. rer. nat.)

der
Naturwissenschaftlichen Fakultät II
Chemie, Physik und Mathematik
der Martin-Luther-Universität
Halle-Wittenberg

vorgelegt von
Pascal Püllmann
geboren am 18.01.1993 in Seesen

The experimental work presented within this thesis has been conducted at the Leibniz-Institute of Plant Biochemistry (IPB) in Halle (Saale) within the period of April 2017 to May 2021.

First Reviewer and Supervisor: Jun. Prof. Dr. Martin J. Weissenborn (Martin-Luther Universität Halle-Wittenberg)

External Reviewer: Prof. Dr. Bernhard Hauer (Universität Stuttgart)

Date of submission: 28th May 2021

Date of public defence: 25th October 2021

“Life may be chemistry, but it’s a special circumstance of chemistry. Organisms exist not because of reactions that are possible, but because of reactions that are barely possible. Too much reactivity and we would spontaneously combust. Too little, and we would turn cold and die. Proteins enable this barely possible reactions, allowing us to live on the edges of chemical entropy—skating perilously, but never falling in.”

Siddhartha Mukherjee, *The Gene: An intimate history*

Acknowledgement

The making of this thesis has been an incredible four-year journey involving countless people who have supported me and without which I would not have stand a chance in making it through this extraordinary time. Therefore, I will try my best to squeeze everyone into this acknowledgement– it is going to be a long one.

Firstly, I am indebted to Jun. Prof. Dr. Martin Weissenborn for accepting me into his group and the trust he has put into my work and ideas ever since I have set foot in the lab. Becoming a PhD student occurred a bit by accident through an intense weekend of writing a short notice grant proposal for a scholarship, retrospectively however, it has been an intense but very fruitful time. I am further grateful for always finding a rapid way for financing my salary, abroad stays, conferences and some new ideas. In this regard also thank you for having me for an additional year as a Postdoc, thereby promoting some follow up ideas on yeast systems and UPO catalysis awaiting to be explored.

I am especially grateful towards Prof. Dr. Bernhard Hauer (University of Stuttgart) for kindly taking the position of external reviewer and his quick correspondence.

It has been a remarkable experience to set up the Nemo lab from day 1 onward, for which I am infinitely indebted towards my beloved first hour lab mates and friends Anja Knorrscheidt and Michelle Kammel. All three of us being naïve, fresh, motivated PhD students we have spent countless hours building the systems from scratch and thereby managed to put the lab on solid pillars for the next generations to come. I could not have made it throughout this intense and (experimentally) rather unsuccessful times without you two. I would like to thank Anja for a lot of leisure time outside of the lab, including a lot of legendary IPB, NatFusion or WG parties to remember- in most cases at least connected to a partially coherent memory. If I could just take just one thing out of these four years, it would be our friendship, thank you for everything!

Nicole Hünecke has been elemental to shape the current form and method portfolio of the Nemo group and has been the good soul of the lab ever since. Thank you so much for keeping the lab running smoothly by taking care of all this small yet essential, often overlooked things and having incredible patience with often annoying inquiries of stressed-out PhD students. The later arriving Nemos including Eugen, Robert, Judith and Dominik are a great new generation to share time and ideas with.

I am indebted to Prof. Miguel Alcalde (CSIC, Madrid) for taking me in as an intern in autumn 2017 to learn some UPO and directed evolution methodologies. Despite being a short stay of a couple of weeks, it kickstarted my PhD project and has been the foundation of all the follow up work on yeast secretion systems and UPO production. Thanks also to Patri, Pati, Ivan and David for the fun times in the lab.

My gratitude goes further towards Prof. Frank Hollmann (TU Delft) for accepting me as an intern learning about reaction concepts of UPO catalysis and Wuyuan Zhang for supervising me during this period. It has been a truly inspiring experience in the BOC group.

The IPB has been an extraordinary place to work at in the last four years. Besides the very memorable Christmas, summer, PhD and post-defense parties also the time spent working has been truly inspiring. The successful build-up of the lab was mainly based on the generous help of people from other departments providing countless plasmids, strains and knowledge. In this regard I would like to thank Dr. Sylvestre Marillonnet and Ramona Grützner for incredible support and fruitful collaboration regarding plasmid parts and Golden Gate circuits. Dr. Martin Dippe, Prof. Bernhard Westermann and PD Dr. Thomas Vogt for remaining patient during my numerous questionnaires and sharing valuable tips and insights from their extensive pool of experience. Another fruitful collaboration has been the work with Dr. Steffen Neumann and Chris Ulpinnis on the Golden Mutagenesis tool. Special thanks to Chris for spending several late-night but still fun-time primer coding sessions in E2 and thereby causing essential IPB crisis situations such as the “Döner-Gate”. And for being a close friend ever since enjoying the perks of good beer and bad movies.

A lot of IPB Members, some of them becoming friends throughout the years, who have made the time at the IPB worthwhile through casual and scientific talks and shared (party) experiences. This list includes Tom, Kathleen, Arianne, Jara, Ulschan, Micha, Svitlana, Paul, Tristan, Evelyn, Anja E., Haider and Aldrin. I would like to thank the great IPB IT and administrative staff, which by rapidly solving issues of technical troubleshooting and paperwork created a very efficient working atmosphere. Special thanks to Ines Stein for being a great administrative help and interesting dialog partner throughout the years.

The Graduiertenförderung Saxony Anhalt for generously financing the first three years of my dissertation project through a PhD scholarship.

I would especially like to thank my closest friends that have made the 10 years in Halle a great experience, by now slowly scattering towards new places. Thanks to all for listening to all the small and big complains I had in the last four years and for your expressed patience by staying friends, nevertheless. This includes Hendrik, Anja, Johann, Julius, Barbara, Jann, Corinna, Johannes, Alex, Tebbe and Tom. Thank you for the splendid times!

The last and biggest chunk of gratitude is reserved for my family. I am incredible grateful towards my parents for their continuous emotional support throughout my studies and PhD work and for placing an infinite amount of trust towards the decisions I have made. Big thanks towards my brother, who repeatedly showed me that there are way better options to employ yeasts in a meaningful, tasteful fashion than to use them as expression hosts.

List of Abbreviations

General remarks: Amino acids are abbreviated either by their respective one or three letter code according to IUPAC guidelines. Chemical elements are abbreviated according to their respective element symbol in the periodic table.

aa- amino acid	<i>Mhi</i> UPO- UPO from <i>Myceliophthora hinnulea</i>
<i>Aae</i> UPO- UPO from <i>Agrocybe aegerita</i>	<i>Mwe</i> UPO- UPO from <i>Marasmius wettsteinii</i>
ABTS- 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)	NADH- nicotinamide adenine dinucleotide
APO- aromatic peroxygenase	MS- mass spectrometry
ARS- autonomously replicating sequence	NBD- 5-nitro-1,3-benzodioxole
BM ₃ - cytochrome P ₄₅₀ from <i>Bacillus megaterium</i>	PCR- polymerase chain reaction
bp- base pair	PVA- polyvinyl alcohol
<i>Cci</i> UPO- UPO from <i>Coprinopsis cinerea</i>	PEG- polyethylene glycol
<i>Cgl</i> UPO- UPO from <i>Chaetomium globosum</i>	ps- picosecond
<i>Cvi</i> UPO- UPO from <i>Chaetomium virescens</i>	<i>P_{Hp}DHAS</i> - dihydroxyacetone synthase promoter
CO- carbon monoxide	<i>P_{Hp}FMD</i> - formate dehydrogenase promoter
COP I- coatomer I	<i>P_{Hp}MOX</i> - methanol oxidase promoter
COPII- coatomer II	<i>Pp</i> - <i>Pichia pastoris</i>
CPO- chloroperoxidase	<i>P_{Pp}ALD₄</i> - aldehyde dehydrogenase promoter
<i>Cra</i> UPO- UPO from <i>Coprinus radians</i>	<i>P_{Pp}AOX₁</i> - alcohol oxidase 1 promoter
CYP- cytochrome P ₄₅₀ enzyme	<i>P_{Pp}CAT₁</i> - catalase 1 promoter
<i>Dca</i> UPO- UPO from <i>Daldinia caldariorum</i>	<i>P_{Pp}DAS₁</i> - dihydroxyacetone synthase 1 promoter
DMP- 2,6-Dimethoxyphenol	<i>P_{Pp}DAS₂</i> - dihydroxyacetone synthase 2 promoter
<i>ee</i> - enantiomeric excess	<i>P_{Pp}FDH₁</i> - formate dehydrogenase 1 promoter
eGFP- enhanced green fluorescent protein	<i>P_{Pp}FLD₁</i> - formaldehyde dehydrogenase 1 promoter
FAD- flavine adenine dinucleotide	<i>P_{Pp}PMP₂₀</i> - peroxisomal glutathione peroxidase promoter
FMN- flavine mononucleotide	SRP- signal recognition pattern
GC- gas chromatography	TOF- turnover frequency
HDM- human drug metabolite	TON- turnover number
<i>Hin</i> UPO- UPO from <i>Humicola insolens</i>	<i>Tte</i> UPO- UPO from <i>Thielavia terrestris</i>
HIV- human immunodeficiency virus	UPO- unspecific peroxygenase
<i>Hp</i> - <i>Hansenula polymorpha</i>	
kcal- kilocalorie	
MUT- methanol utilisation pathway	
<i>Mro</i> UPO- UPO from <i>Marasmius rotula</i>	
<i>Mfe</i> UPO- UPO from <i>Myceliophthora fergusii</i>	
<i>Mth</i> UPO- UPO from <i>Myceliophthora thermophila</i>	

Summary

The selective oxyfunctionalisation of non-activated carbon atoms remains a grand challenge within the field of classical organic synthesis. Nature has developed a versatile toolbox of diverse enzyme classes which are capable of the efficient regioselective installation of hydroxyl-groups, in many cases also combined with high stereoselectivities. One enzyme class, which has attracted keen interest within the field of oxyfunctionalisation biocatalysis in recent years are fungal unspecific peroxygenases (UPOs).

Despite gaining outstanding attraction by combining high enzyme stability and activities, while solely depending on hydrogen peroxide as simple co-substrate, the widespread usage of UPOs still remains greatly hampered. This fact can be predominantly attributed to their challenging heterologous production using standard laboratory hosts due to their occurrence as secreted, disulfide-linked and extensively glycosylated enzymes.

The primary aim of this thesis was therefore to develop flexible modular systems for the secretion of reported and novel peroxygenases in the yeast organisms *Saccharomyces cerevisiae* and *Pichia pastoris* to broaden the panel of recombinant UPOs. In a first project, we have developed a modular Golden Gate cloning system coined Golden Mutagenesis allowing for the rapid and inexpensive construction of complex mutagenesis libraries, aided by an implemented automated primer design online design tool.

Building upon the intrinsic modular logic of Golden Mutagenesis we subsequently expanded the system towards episomal and genomically integrated protein production in *S. cerevisiae* and *P. pastoris*. By identifying the signal peptide as crucial factor for alteration and implementing a flexible signal peptide shuffling module (17 possible combinations), we could boost the secretion of previously known enzymes and produce four UPOs for the first time recombinantly in yeast. Two out of these enzymes were thereby derived from secretome data and have not been annotated as peroxygenases before. Extensive signal peptide shuffling and subsequent utilisation of the constructed *P. pastoris* system led to the highest reported recombinant UPO volumetric shake flask yields to date. We could conclude this study by application of the respective novel UPOs in a proof-of-concept preparative scale production of an enantiopure hydroxylated compound of high pharmaceutical interest.

Combining the previously developed Golden Mutagenesis technique, the modular yeast UPO secretion system and initially characterised UPOs led to the subsequent successful execution of multiple enzyme evolution projects. Firstly, six novel long-type UPOs could be identified through genetic shuffling of three wild type UPO genes in combination with a versatile high-throughput GC-MS analysis method. Utilising the previously discovered UPO derived from *Myceliophthora thermophila* (*Mth*UPO), the wild type enzyme was consecutively evolved towards the chemo- and regioselective aromatic hydroxylation of naphthalene and substituted derivatives, as well as the benzylic hydroxylation of indane and 1,2,3,4-tetrahydronaphthalene.

Within a second project, variant libraries of *Mth*UPO were tested towards the conversion of multiple non-activated substrates employing an extended version of the previously established high-throughput GC-MS analysis method. Subsequent analysis led to the identification of variants with altered product formations as well as abolished substrate conversions. When converting octane, one variant exhibited substantial formation of 1-octanol, a reaction product that cannot be assessed when utilising the *Mth*UPO wild type enzyme as catalyst.

In the concluding project the previously established modular UPO secretion system in *P. pastoris* was further expanded by including an additional promoter shuffling module. By combining eleven strong methanol inducible promoter with the previously introduced panel of 17 signal peptides up to 187 diverse, unique combinations for target protein secretion can be assessed. Harnessing this system, we could optimise the yield of two previously investigated UPOs and produce three novel peroxygenases for the first time recombinantly in yeast, surpassing previously reported recombinant yields in *E. coli* by approximately 600 %.

Zusammenfassung

Im Feld der organischen Chemie stellt die selektive Oxyfunktionalisierung von nicht aktivierten Kohlenstoff-Atomen eine der verbleibenden großen Herausforderungen der synthetischen Chemie dar. Die natürliche Evolution hat für diese Reaktivität ein vielfältiges Set an verschiedensten Enzymklassen innerhalb der Organismen hervorgebracht. Diese Enzyme ermöglichen die effiziente und regioselektive Installation von Hydroxylgruppen innerhalb von Molekülen, häufig werden dabei zudem hohe Stereoselektivitäten erreicht. Eine Enzymklasse, welche in den vergangenen Jahren ein großes Interesse im Feld der biokatalytischen Oxyfunktionalisierung hervorgerufen hat, sind die pilzlichen unspezifischen Peroxygenasen (UPOs).

Trotz dieses immensen Interesses, welches sich aus der Kombination von allgemein hohen Enzymstabilitäten und -aktivitäten, bei gleichzeitiger alleiniger Abhängigkeit von Wasserstoffperoxid als kostengünstigem Co-Substrat ableitet, ist die momentane Verbreitung von UPOs im Feld der Biokatalyse stark limitiert. Diese Beobachtung lässt sich primär auf die herausfordernde heterologe Produktion von UPOs, aufgrund des natürlichen Vorkommens als sekretierte, Disulfid-verknüpfte und stark glykosylierte Enzyme, zurückführen.

Das primäre Ziel dieser Dissertationsarbeit bestand daher in der Expansion des momentan verfügbaren rekombinanten UPO Portfolios durch die Entwicklung von flexiblen, modularen Systemen für die Produktion und Sekretion von beschriebenen und neuartigen Peroxygenasen in den Hefeorganismen *Saccharomyces cerevisiae* und *Pichia pastoris*. Im Verlauf eines ersten Projektes haben wir mit Golden Mutagenesis ein modulares Golden Gate Klonierung basiertes System entwickelt. Golden Mutagenesis erlaubt die schnelle und kostengünstige Konstruktion von komplexen Mutagenese-Bibliotheken und wird zusätzlich durch die Implementierung eines automatisierten frei verfügbaren Primer-Design Programms unterstützt.

Aufbauend auf der intrinsischen Logik des konstruierten Golden Mutagenesis-Systems wurde es hinsichtlich der Proteinproduktion in *S. cerevisiae* und *P. pastoris*, unter Verwendung episomaler und genomisch integrierter Expressions-Konstrukte, erweitert. Durch die Identifizierung des respektiven Signalpeptids als entscheidenden Faktor für eine Variation und damit verbundener Implementierung eines Signalpeptid-*shuffling* Modules (17 mögliche Signalpeptid-Kombinationen), konnten wir die Sekretion von bekannten UPOs steigern, sowie vier UPOs zum ersten Mal heterolog in beiden Hefeorganismen herstellen. Zwei Enzyme aus diesem neuen Set entstammen Sekretom-Datensätzen und wurden zuvor nicht als UPOs klassifiziert. Tiefgehende Signalpeptid-Optimierung mittels genetischen *shufflings* innerhalb des konstruierten *P. pastoris* Sekretionssystems resultierte in den bislang höchsten beschriebenen rekombinanten UPO-Ausbeuten (mg/L) innerhalb von Schüttelkolben-Kultivierungen. Wir konnten diese Studie mit der Anwendung von mehreren neu-

beschriebenen Peroxygenasen im Rahmen einer Machbarkeitsstudie für die stereoselektive, präparative Synthese einer hydroxylierten Verbindung mit hoher pharmazeutischer Relevanz erfolgreich abschließen.

Basierend auf der Kombination der zuvor etablierten Golden Mutagenesis Technologie, des modularen UPO-Sekretionssystems in Hefe und den initial beschriebenen UPOs konnten nachfolgend mehrere Enzym-Evolutionsprojekte erfolgreich durchgeführt werden. In einer ersten Studie konnten sechs neuartigen *long-type* UPO-Chimären durch die genetische Kombination von drei Wildtyp-UPO Gensequenzen konstruiert und mithilfe eines versatilen konstruierten GC-MS Hochdurchsatzverfahrens als aktive Enzyme identifiziert werden. Unter Verwendung einer zuvor entdeckten Wildtyp-UPO aus *Myceliophthora thermophila* (*MthUPO*) als Ausgangspunkt konnte das Enzym in mehreren Mutagenese-Runden hinsichtlich einer chemo- und regioselektiven Hydroxylierung von Naphthol sowie substituierten Derivaten sowie der benzyllischen Hydroxylierung von Indan und Tetrahydronaphthalin evolviert werden. Im Rahmen eines zweiten Projektes wurden Varianten-Bibliotheken von *MthUPO* mithilfe einer weiterentwickelten Version des zuvor etablierten GC-MS Hochdurchsatzverfahrens hinsichtlich der Umsetzung von mehreren nicht-aktivierten Substraten untersucht. Eine nachfolgende Analyse konnte Enzymvarianten, welche veränderte Produkt-Profile generieren, sowie einzelne Substrate nicht umsetzen können, identifizieren. Bei der Umsetzung des linearen Alkans Oktan wurde in Fall einer Enzymvariante eine substantielle Formation des terminalen Alkoholprodukts 1-Oktanol beobachtet, ein Reaktionsprodukt, welches unter Verwendung des Wildtyp-Enzyms nicht erhalten werden kann.

In einem abschließenden Projekt wurde das zuvor etablierte modulare UPO Sekretionssystem in *P. pastoris* durch ein zusätzliches Promoter-*shuffling* Modul erweitert. Durch die Kombination von elf starken, Methanol-induzierbaren Promotoren mit dem zuvor eingeführten Set von 17 Signalpeptiden können bis zu 187 höchst diverse Kombinationen für die Sekretion eines Zielproteins generiert und getestet werden. Unter Verwendung dieses kombinierten Systems konnten wir die Ausbeuten von zwei zuvor untersuchten UPOs steigern, sowie drei neue Peroxygenasen zum ersten Mal rekombinant in Hefe herstellen und zudem im Fall einer UPO zuvor berichtete rekombinante Mengen unter Verwendung von *E. coli* um circa 600 % steigern.

1. Introduction

1.1 Enzymatic C–H oxyfunctionalisation

The conversion of C(sp³)–H bonds to C(sp³)–OH bonds and its further oxidised derivatives can substantially impact the properties of the overall molecule, such as solubility and polarity as well as its interaction with other biomolecules¹. Well known examples of this effect include the divergent taste sensations of the sesquiterpene (+)-valencene (taste of orange) and its keto derivative nootkatone (taste of grapefruit), which can be assessed by means of chemical or enzymatic oxidation¹⁻³. Employing classical chemical synthesis the targeted oxyfunctionalisation of specific, single carbon atoms within complex molecules can be rather challenging due to the high stability of C(sp³)–H bonds and similar chemical properties of multiple carbon atoms⁴. Recent research on iron based small molecule catalysts has led to the development of methods for the targeted hydroxylation of hydrocarbons and natural product precursors, significantly expanding the toolbox and understanding of selective C(sp³)–OH bonds installation within challenging molecules^{5,6}.

Nature has developed a versatile panel of enzymes, which are capable of specific C–H oxyfunctionalisation, widely distributed over all kingdoms of life. Due to their distinct three-dimensional fold structures and defined catalytic mechanisms, enzymes can enable precise control of stereoselectivity and regioselectivity of a reaction. This aspect can be considered as a crucial benefit of enzymes, since this control is challenging to achieve employing classical synthesis chemistry methodologies as mentioned before⁴. Based on this benefit and being considered as “green” alternative to classical chemistry, which often necessitates the use of toxic chemicals, high pressure and -temperature, biocatalysis has attracted a keen interest in recent years. Recent major breakthroughs of biocatalysis within the field of industrial chemistry include the engineering of a transaminase for a highly active and stereoselective amination leading to the antidiabetic compound sitagliptin⁷ and the development of an *in vitro* cascade, harnessing nine enzymes for the manufacture of the HIV treatment drug candidate islatravir⁸.

Within the field of C–H oxyfunctionalisation, a spotlight has been the enzymatic *in vitro* synthesis of the antimalarial drug precursor artemisinic acid⁹, which includes the regioselective three-step oxidation by the sequential action of one P450 cytochrome enzyme. In recent years, hydroxylating enzymes (hydroxylases) have been incrementally employed in chemoenzymatic synthesis workflows for the installation of regio- and stereoselective oxyfunctionalisations, within amongst other the scope of the synthesis of macrolide antibiotics¹⁰, peptide antibiotics¹¹ and meroterpenoids¹² on a preparative scale. The natural function of hydroxylating enzymes can be as versatile as the catalytic mechanism of these enzymes. In certain extremophilic organisms' hydroxylases are crucial for the conversion of simple carbon molecules as primary energy source. In some thermophilic *Geobacillus* species linear, long-chain alkanes (C₁₅-C₃₆) can be used as sole

carbon source for proliferation and are hydroxylated by the action of flavin-dependent metal free, alkane monooxygenases¹³. Another prominent example are methane monooxygenases, complex multi-domain enzyme systems relying either on di-iron or copper ions centre for hydroxylation^{14,15}. These enzymes occur in methanotrophic bacteria, enabling them to thrive solely on methane, using the simplest hydrocarbon molecule as sole carbon source and thereby overcoming the highest bond dissociation energy (105 kcal/mol at 298 K) of all sp³ C–H bonds¹⁶. Other copper utilising hydroxylases are the recently discovered *lytic polysaccharide monooxygenases*, which have gained substantial industrial interest due to their ability to aid the degradation of recalcitrant biopolymers such as cellulose and chitin¹⁷. However, most enzymes that are capable of hydroxylation reactions are relying on iron-oxygen complexes as active species, including the classes of α -ketoglutarate-dependent dioxygenases¹⁸ (mononuclear non-heme iron) and Rieske-type oxygenases¹⁹ (iron-sulfur cluster).

The arguably most studied class of hydroxylating enzymes are the heme-iron containing cytochrome P450 enzymes (CYPs) which are named after their characteristic absorption maximum of the reduced CO bound heme-thiolate form²⁰ and have been firstly described in the 1950s. Currently there are more than 300000 annotated sequences of CYPs curated, which are distributed over nearly all kingdoms of life²¹. In animals, CYPs are mostly known for being a key player of oxyfunctionalisation of xenobiotic substances, such as medicinal drugs leading to the formation of their bioactive derivatives²². In plants, they substantially contribute to the vast diversity of primary and secondary metabolism products, including hormones, defence compounds, flavour compounds and many more. Those compounds exhibit regio- and stereoselective oxyfunctionalisations, which are installed by the action of highly-specialised CYPs^{23,24}. On an industrial scale, CYP catalysed reactions are harnessed due to their potential high selectivity and implemented amongst other within the synthesis of artemisinic acid⁹, 4-hydroxyisophorone²⁵ and pravastatin²⁶. However, despite the tremendous appeal and demand of assessing hydroxylated compounds, the occurrence of CYPs within industrial processes remains extremely limited. This observation can be rationalised by encountered drawbacks of CYPs, including the dependence on redox partner enzymes for NAD(P)H supply, low enzyme stability and activity resulting in low product space-time yields, which can be a direct exclusion criteria for industrial processes²⁷⁻²⁹.

1.2 Unspecific peroxygenases (UPOs)

In 2004 a novel class of hydroxylation biocatalysts was firstly described. Naturally secreted from the basidiomycetous fungus *Agrocybe aegerita* the first description of this enzyme classified it as haloperoxidase, based on the hydrogen peroxide fuelled conversion of the classical peroxide substrates veratryl alcohol, ABTS and DMP as well as bromination and chlorination of MCD³⁰. Further substrate testing and conversion of the simple aromatic compounds toluene and

naphthalene prompted the reclassification as aromatic peroxygenase (APO)³¹. Based upon follow up work on reactivities of this enzyme the classification was altered once again, leading to the currently used term of unspecific peroxygenase (UPO)³². UPOs are listed under the accession number EC 1.11.2.1 within the enzyme nomenclature database, based on their oxidoreductase classification (1.11.2.1) and their utilisation of hydrogen peroxide as electron acceptor (1.11.2.1)³³. Respective UPOs are named based on their origin, deriving one letter from the genus classification and two letters from the species identifier. The UPO originating from *Agrocybe aegerita* is therefore called *AaeUPO*³³.

1.2.1 Reaction mechanism and enzyme structure

In 2005 spectroscopic measurements of the resting state (λ_{max} : 420 nm) and the reduced CO bound heme-adduct ($\lambda_{\text{max}} \sim 450$ nm), being analogous to the characteristics of CYP enzymes, pointed towards the occurrence of *AaeUPO* as heme-thiolate enzyme with cysteine as axial iron ligand³¹. Based on this observations and the then known reaction spectra of the enzyme, UPOs have been considered a missing link between heme-thiolate peroxidases such as the chloroperoxidase derived from *Caldariomyces fumago* and heme-thiolate CYPs³¹. Subsequent analysis of genomic DNA and mRNA pools³⁴ from *Agrocybe aegerita* could identify the coding sequence of *AaeUPO* and further strengthen the hypothesis of an axial cysteine heme ligand through the occurrence of a conserved PCP motif also observed in the sequence of a second reported UPO (*CraUPO*; *Coprinellus radians*)³⁵. A breakthrough in the rationalisation of obtained reactivities has been the first report of a crystal structure of *AaeUPO* in 2013³⁶.

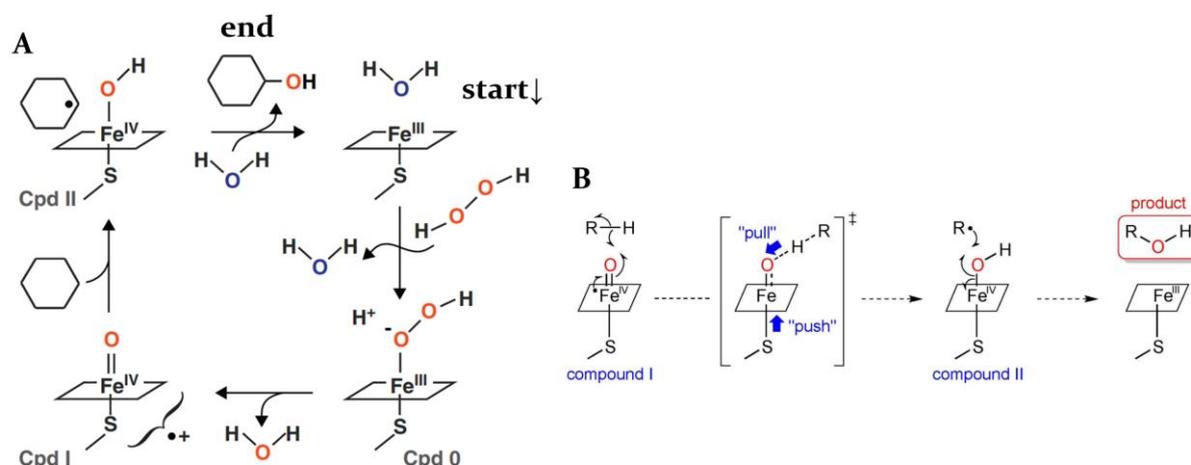

Figure 1: Catalytic cycle of UPO catalysed alkane hydroxylation (A) adapted from Hofrichter and Ullrich³³ and "push and pull" effect in heme-thiolate enzymes (B) adapted from Fessner³⁷

Besides the tremendous knowledge gain through the obtained crystal structure³⁶, further experimental investigations of the UPO reaction cycle (Figure 1A) were undertaken by the means of fast kinetic stopped-flow and radical clock experiments³⁸⁻⁴¹. The derived model of the catalytic

cycle is congruent with the so-called peroxide shunt pathway that has been observed in case of certain CYPs, solely using hydrogen peroxide to generate the reactive iron-oxygen species⁴². In the resting state water is bound as distal ligand to the ferric iron (Fe^{3+}). In a second step (Figure 1A) water is replaced by hydrogen peroxide most likely leading to the short-lived negatively-charged intermediate compound o, which has so far not been finally proven for UPOs but for the closely related heme-thiolate chloroperoxidase⁴³. Upon the proton transfer from a conserved glutamate (E196) residue³⁶ hydrogen peroxide is heterolytically cleaved under electron re-arrangement to form the key oxo-ferryl intermediate compound I (Fe^{4+}). *Aae*UPO compound I formation and decay could be extensively studied by fast spectroscopic stopped-flow measurements^{39,40}. Further studies on the conversion of compound I (Cys-S- $\text{Fe}^{4+}=\text{O}$) to its reduced ferryl compound II form (Cys-S- $\text{Fe}^{4+}-\text{OH}$) revealed remaining C-H scission activity, thereby being the first described enzyme capable of C-H activation in its compound II form⁴. Within the natural cycle, compound I formation is followed by a proton abstraction from the substrate leading to the formation of compound II and an alkyl radical within the active site³³. The alkyl radical rapidly recombines with compound II to form the hydroxylated product (cyclohexanol; Figure 1 A), thus concluding the UPO reaction cycle³⁸. Radical clock experiments of *Aae*UPO by using norcarane as substrate, confirmed a life time of 9.4 ps for the generated substrate radical³⁸.

UPOs as well as CYPs utilise a cysteine-coordinated heme as active species, which leads to a “push and pull” effect (Figure 1B) in the course of catalysis³⁷. The underlying features of cysteine as axial heme ligand, enabling the breakage of strong C-H bonds (~100 kcal/mol) of hydrocarbon molecules has remained a riddle for many years⁴⁴. Thiolate is a strong electron donor to iron, therefore pushing electrons towards the intermediate compound I^{44,45}. Therefore, the basicity of the ferryl oxygen ($\text{pK}_a \sim 12$) is greatly enhanced, rendering it approximately 8.5 units higher than the basicity within histidine-ligated heme systems⁴⁴. This strong basicity (pull) slightly favours the C-H activation over the oxidation of aromatic residues⁴⁴, predominantly tyrosine, within the active site by compound I, which leads to oxidative damage and unproductive decay of compound I. In summary, it is postulated that this trade-off between lowered redox-potential and high basicity of the ferryl oxygen renders thiolate-heme catalysts suitable for C-H bond cleavage, while suppressing unproductive long-range electron transfer events^{44,45}.

To date solely two crystal structures of wild type unspecific peroxygenases have been solved, therefore substantially impeding the detailed understanding and rationalisation of parameters such as substrate preference, regioselectivity and stereoselectivity of the enzyme class. Besides the structure of *Aae*UPO³⁶, in 2017 the structure of a UPO (*Mro*UPO) derived from *Marasmius rotula* (unpublished work) was deposited, which was firstly characterised in 2011⁴⁶. Both enzymes share only a low sequence identity (30 %) and represent members of the two

currently characterised enzyme subgroups, namely the long-type UPOs (*Aae*UPO) and short-type UPOs (*Mro*UPO).

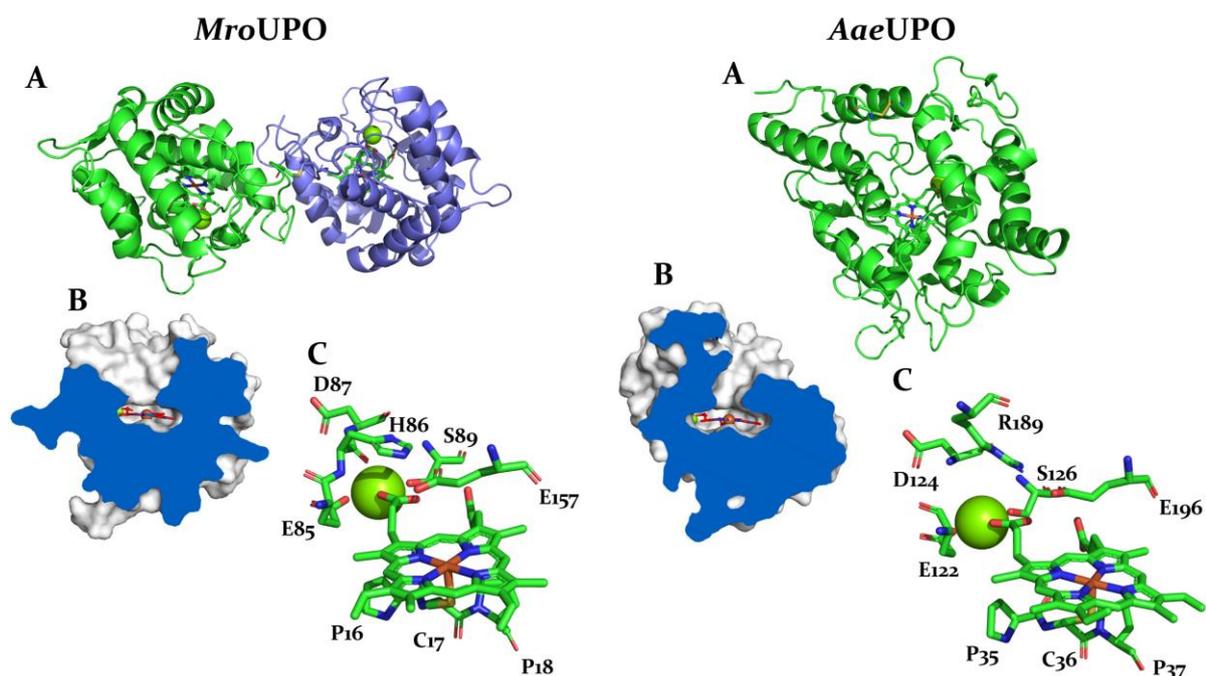

Figure 2: (A) Crystal structure of *Mro*UPO (left; pdb entry: 5FUK) and *Aae*UPO (right; pdb entry: 2YOR) (B) active site and channel cross-section of both enzymes adapted from Ullrich *et al.*⁴⁷ (C) Crucial aa residues within the active site

Based on their primary sequence, UPOs can be readily classified into the two respective groups. Long-type UPOs typically contain around 330 amino acids, whereas short-type UPOs contain approximately 240 amino acids. Structurally, based on the two crystal structures available, great differences can be observed (Figure 2A). *Mro*UPO forms a homo-dimeric structure, which is linked by an intermolecular disulfide linkage of two cysteine residues (C226–C226), which are located within the C-terminal region of the enzyme. An observation that is also consistent in the case of other discovered short-type UPOs, namely *Cgl*UPO⁴⁸ (*Chaetomium globosum*), *Cvi*UPO⁴⁹ (*Chaetomium virescens*) and *Dca*UPO⁴⁹ (*Daldinia caldariorum*). Long-type UPOs occur as a monomer and contain a C-terminal intramolecular disulfide linkage (C278–C319), which is considered to be a key stabilizing factor within the flexible C-terminus region³⁶. In general, UPOs are occurring as secreted, strongly glycosylated (10–40 % carbohydrate content) enzymes within their natural host⁵⁰. Glycosylation generally proceeds as N-glycosylation (asparagine residues) of a high-mannose type⁵⁰.

Tangential cross-sections of the active site and the substrate access channel of both enzymes (Figure 2B) reveal subtle differences. The substrate channel of *Aae*UPO is rather long but narrow in comparison, being “carafe-shaped”⁴⁷. In contrast *Mro*UPO possesses a rather short (4 Å shorter than *Aae*UPO), but wider (up to 5 Å) access channel, which can be characterised as a frustum⁴⁷. Furthermore, the amino acid composition of the channel varies substantially, which

is reflected by the respective substrate preference and reactivities of the enzymes, as will be discussed in detail within the following sections. In case of *Aae*UPO, the channel is shaped by 10 rather rigid aromatic side-chain residues (9x Phe; 1x Tyr)³⁶, whereas in case of *Mro*UPO aliphatic side-chain residues (7x Ile; 2x Leu; 1x Ala)⁴⁷ form the active site. Regarding catalytically conserved, crucial residues (Figure 2C) both enzyme subtypes do not differ substantially. In both cases the axial cysteine ligand is flanked by two rigid prolines, thereby aiding positioning of the cysteine thiolate towards the heme iron⁵⁰ and forming a highly conserved PCP-motif that can be found in all described UPOs to date. Heterolytic cleavage of the hydrogen peroxide which leads to the formation of compound I is catalysed by the conserved acid catalyst glutamate E157 (short-type) and E196 (long-type), which is positioned parallel to the heme plane, just above the central iron. Differences occur in the case of the glutamate charge-stabilising amino acid, being an arginine (R189) in long-type UPOs, whereas in short-type UPOs a conserved histidine residue can be found (H86), both counteracting as base to the acid catalyst glutamate^{36,50}. Another common feature is the occurrence of a magnesium ion (Figure 2C; green sphere) in direct proximity to the heme b plane. The magnesium is complexed by a conserved amino acid triad of glutamate (85/122), aspartate (87/124) and serine (89/126)^{36,50}. The magnesium is generally believed to stabilise the heme, which exhibits considerable ring-strain, by the installation of salt bridges between the positively charged ion and the two negatively charged heme carboxylate side chains⁵¹.

1.2.2 Spectrum of reactivities

Despite being a rather recently introduced enzyme class, that was firstly describe just 17 years ago, already a broad range of more than 400 convertible diverse substrates have been reported, also shaping the enzyme name towards “unspecific”. In recent years UPOs have also been referred to as “swiss army knives of oxyfunctionalisation”⁵².

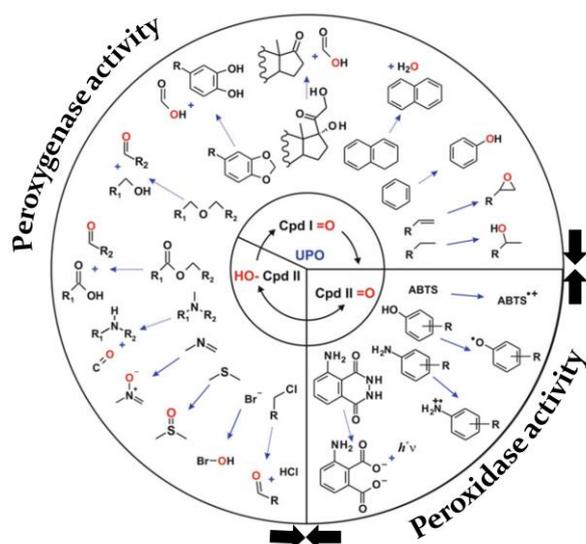

Figure 3: Overview of UPO catalysed reactions adapted from Hofrichter *et al.*⁵⁰ subdivided into one-electron oxidations (peroxidase activity) and two-electron oxygen transfer reactions (peroxygense activity)

In general, the reactions of UPOs can be grouped into two classes (Figure 3), namely one-electron oxidations (peroxidase activity) and oxygen-incorporating two-electron oxidations (peroxygenase activity). The occurring peroxidase activity represents a pronounced disadvantage for application since it can substantially deplete the pool of hydroxylated products by further conversion to unwanted side-products. The conversion of the aromatic compound naphthalene can serve as fitting example for this dual reactivity. In a first step naphthalene is hydroxylated to 1- and 2-naphthol (peroxygenase activity), both serving as substrate for subsequent one-electron oxidations (peroxidase activity) leading to the formation of phenoxy-radicals, which can then undergo coupling resulting in the formation of polymeric side-products⁵³.

1.2.2.1 Aromatic Hydroxylation

Aromatic hydroxylation constitutes a special case of UPO catalysed oxyfunctionalisation, since it does not follow the reaction mechanism as previously described (Figure 1A), but rather proceeds via an semi-stable epoxide intermediate, which has been observed to be stable for several minutes in the case of naphthalene⁵⁴ and undergoes subsequent re-aromatization through an NIH shift mechanism leading to the hydroxylated compound^{53,55,56}.

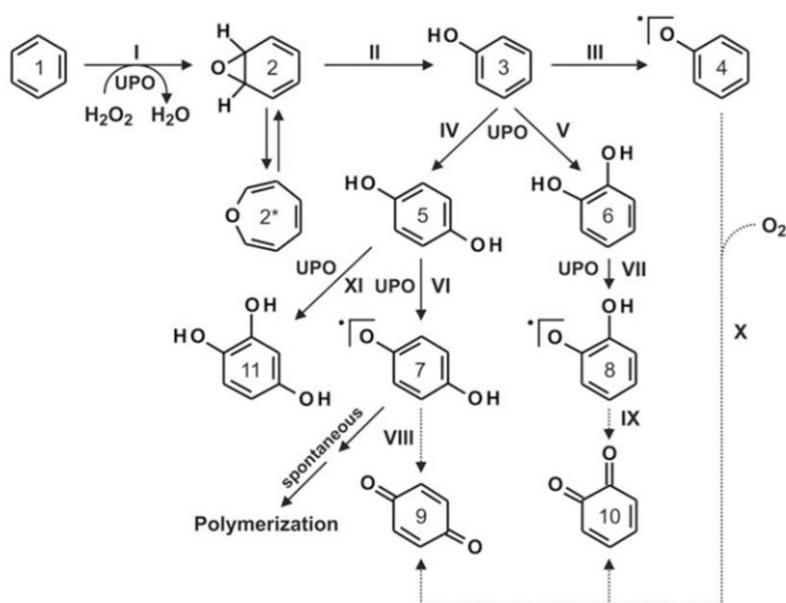

Figure 4: UPO catalysed conversion of benzene adapted from Hofrichter *et al.*⁵⁰

The conversion of benzene (Figure 4) by *Aae*UPO can serve as prime example of aromatic hydroxylation^{50,56}. Benzene (1) is converted to Phenol (3) via an epoxide intermediate (2). Phenol exhibits a more suitable UPO substrate due to the enhanced electron density within the aromatic ring⁵⁶. Subsequent hydroxylation events result in the formation of hydroquinone (5), catechol (6) and 4-hydroxycatechol (11). Due to the occurring peroxidase activity, leading to

Phenoxy-radicals (O \cdot species), further oxidised diketone products, namely para- (9) and ortho-quinone (10) and polymerised adducts can be obtained.

In recent years, besides the described conversion of benzene⁵⁶ and naphthalene^{34,55} a multitude of aromatic hydroxylation reactions of a diverse set of UPOs have been described. Another suitable simple aromatic substrate proved to be toluene, which is converted by *Aae*UPO to a heterogeneous product pool of ring hydroxylation products (*p*- and *o*-cresol) and products modified at the benzylic position (benzylic alcohol, benzaldehyde and benzoic acid)³¹. Subsequent work utilising *Cra*UPO and *Aae*UPO, targeting larger polycyclic aromatic compounds, including dibenzothiophene, fluorene, phenalene, anthracene and pyrene could confirm conversions of these substrates to a heterogeneous product pool of mono- and multi-hydroxylated as well as further oxidised keto products^{57,58}. In a broader study *Aae*UPO and *Mro*UPO were challenged with 40 environment pollutants including chlorinated benzenes, nitroaromatic compounds and polycyclic aromatic hydrocarbons⁵⁹. Out of this large panel 35 compounds could be successfully converted by at least one UPO⁵⁹. Since the natural function of UPOs still remains elusive, based on this study and other work it has been frequently hypothesised that UPOs might play a key role in the detoxification of the fungal microenvironment⁵⁸⁻⁶⁰. Being secreted proteins, solely relying on hydrogen peroxide for activity, which can be supplied by the other secreted enzymes such as aryl-alcohol oxidases⁶¹, UPOs have been considered as “extracellular liver”⁵⁹, also taking their extensively broad substrate spectrum into account.

Regarding their detoxification ability, UPOs have been further characterised for the conversion of pharmaceuticals to their hydroxylated active derivatives (human drug metabolites, HDMs). A crucial process in animal metabolism that is typically occurring within the liver by the action of promiscuous CYP enzymes²². Challenging *Aae*UPO with the conversion of the widely spread β -blocker drug Propranolol and the anti-inflammatory agent diclofenac led to the highly regioselective formation of the HDMs 5'-hydroxypropranolol and 4'-hydroxydiclofenac⁶². The regioselectivity was further exploited for a successful proof of principle study using UPOs in the production of deuterium labelled 4'-hydroxydiclofenac⁶³. A detailed follow up study on pharmaceutical drugs could further broaden the spectrum of aromatic hydroxylation reactions by verifying the conversion of paracetamol, carbamazepine, ibuprofen and tolbutamide⁶⁴.

Naturally occurring, biological aromatic compounds represent another class of compounds that could be shown to be suitable UPO substrates. In a first study in 2011 several flavonoids could be converted in a regioselective manner. Utilising *Aae*UPO the flavonoids apigenin, flavone and luteolin were converted to their respective mono-hydroxylated alcohols (6'-position)⁶⁵. Choosing a three-enzyme panel of *Aae*UPO, *Mro*UPO and *Cci*UPO (*Coprinopsis cinerea*) and the stilbene substrates *trans*-stilbene, pinosylvin and resveratrol, a broad panel of

mono- and di-hydroxylated aromatic products could be obtained⁶⁶. Respective product formations and mixtures were thereby strongly depending on the utilised enzymes, displaying divergent selectivities⁶⁶.

Recent chemoenzymatic studies have exploited the occurrence of the installed intermediate epoxide (Figure 4) during UPO catalysis to enable access to a new synthetic route to a diverse set of trans di-substituted cyclohexadienes⁵⁴. The intermediate arene oxide can be subsequently attacked by a nucleophile, resulting in the creation of two stereocenters, thereby combining biocatalytic activation (epoxidation) and chemical diversification (nucleophilic opening) in an elegant manner⁵⁴.

1.2.2.2 Hydroxylation of sp³ carbon atoms

The most challenging and therefore arguably also most interesting substrate conversions of UPOs represent the oxyfunctionalisation of non-activated sp³ carbon bonds, since the bond dissociation energy in this cases is extremely high, reaching approx. 100 kcal/mol⁶⁶. Therefore, an extraordinarily strong, potent oxidant (compound I) is required for substrate radical formation.

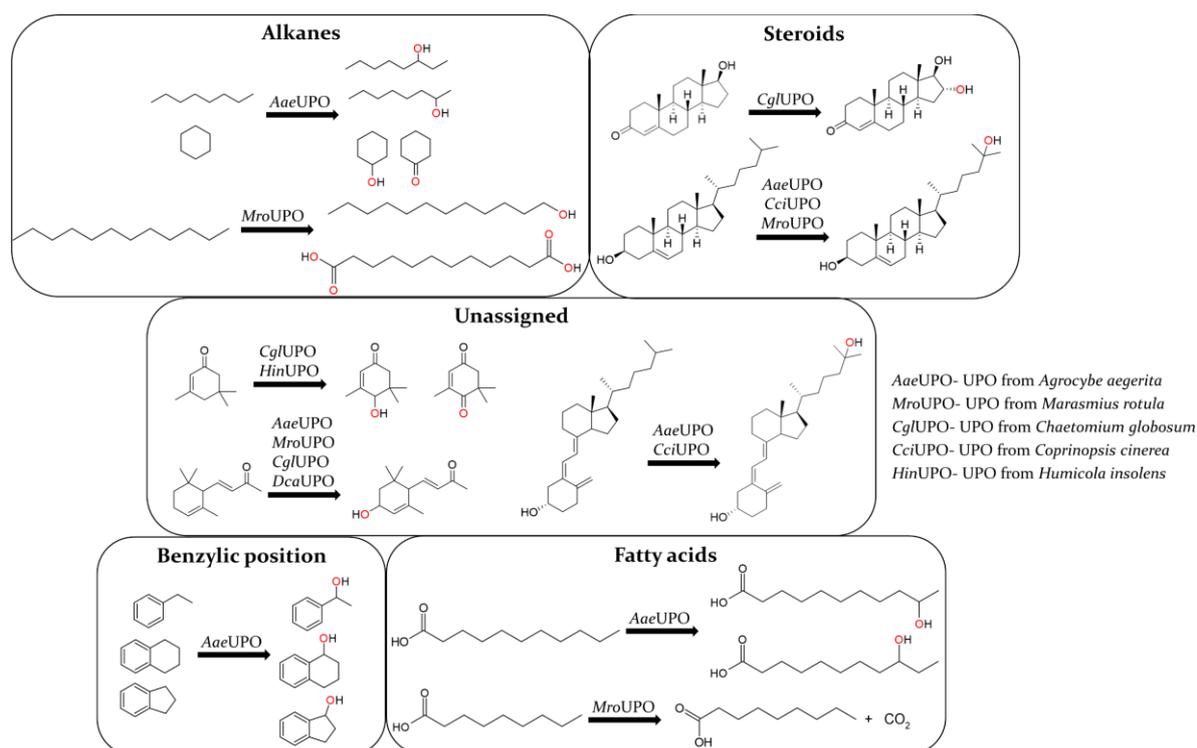

Figure 5: Overview of the most relevant sp³ C–H oxyfunctionalisations catalysed by respective UPO enzymes

As already reflected by the name of “aromatic peroxygenase”, which was commonly used until around 2011, initial studies of this enzyme class predominantly focused on the conversion of aromatic substrates by *AaeUPO* and *CraUPO*. First studies on the conversion of inactivated alkanes were reported in 2011³⁸. *AaeUPO* was found to efficiently catalyse the conversion of

several short alkanes ranging from *n*-propane to *n*-octane to the corresponding alcohols (Figure 5) in 2- and 3-position³⁸. In the case of *n*-heptane and *n*-octane extraordinary high enantiomeric excesses (*ee*) of ≥ 99 % for the 3-alcohol product (*R* enantiomer) could be determined³⁸. Astonishingly, when challenging *Mro*UPO with dodecane as substrate (Figure 5) substantial formation of terminal hydroxylated 1-dodecanol and further oxidations of this product reaching the stage of carboxylic acid could be observed, thereby spanning a reaction range from inert alkanes to dicarboxylic acids⁶⁷.

Using cyclohexane as simple cyclic alkane substrate revealed divergent patterns of hydroxylation (cyclohexanol) and overoxidation (cyclohexanone) employing *Aae*UPO and *Mro*UPO. Whereas *Aae*UPO revealed nearly no overoxidation of the alcohol (2 % of total products), utilising *Mro*UPO led to a substantial occurrence of overoxidation (37 %) ⁶⁸. A similar pattern of *Aae*UPO catalysis was acquired, when testing saturated fatty acids (Figure 5) of comparable chain length (C_{10} and C_{12})⁶⁹. In addition to a small amount of further oxidised products, predominantly the formation of mono-hydroxylated products in ($\omega-1$) and ($\omega-2$) could be shown. Similar results could be obtained when testing *Cci*UPO as catalyst⁷⁰. Once again, *Mro*UPO exhibited greatly differing selectivity when testing decanoic acid (C_{10}) (Figure 5), a substrate that is not known to be efficiently converted by *Aae*UPO. By sequential hydroxylation of the carbon atom adjacent to the carboxyl-function (α -position) reactive keto-intermediates are formed, ultimately leading to the shortening of the fatty acid by one carbon atom and the release of CO_2 ⁷¹. Thereby a pool of shortened carboxylic acid derivatives can be obtained in a sequential manner.

Steroid core structures display another highly interesting class of inactivated hydrocarbons and are a common motif in medicinal drugs. Hydroxylated steroid derivatives are of outstanding interest as functionalised intermediate in drug development and testing and are difficult to selectively install by classical chemical means⁷². Extensive work on the self-sufficient monomeric cytochrome enzyme $P450_{BM3}$ derived from *Bacillus subtilis* has enabled the development of enzyme variants that display extraordinary regioselectivity towards various position within the testosterone core structure⁷³⁻⁷⁵. Due to their comparable reaction profile UPOs have attracted interest regarding selective steroid hydroxylation. A first study has been reported in in 2015, utilising the three UPOs *Aae*UPO, *Mro*UPO and *Cci*UPO (Figure 5) and testing a broad panel of sterols, steroid ketones, steroid hydrocarbons and sterol esters for conversion⁶⁰. It was observed that free sterols (cholesterol, ergosterol, sitosterol etc) are particularly suitable substrates and that hydroxylation occurs within the side-chain of the molecule, nearly selectively at the C_{25} position (Figure 5). All three UPOs were not able to convert the gonane core structure, as in the case of the model compound testosterone no product formation could be obtained. Subsequent computational studies, including docking and protein dynamics simulations could further rationalise the observed conversions^{60,76}. In 2017 the newly

discovered short-type *Cgl*UPO, which also has been the first reported UPO derived from an ascomycete, was the first UPO capable of testosterone conversion⁴⁸. Testosterone could be efficiently converted with 7000 turnover numbers (TON), predominantly forming the 4,5-epoxide (90 % of product) but also the 16- α hydroxytestosterone product (Figure 5), resulting in both cases in excellent (> 98 %) enantioselectivities.

Other recent showcases of relevant C-H activations include the conversion of isophorone and α -ionone (Figure 5). Isophorone was converted by a set of UPOs leading to products 4-hydroxyisophorone and 4-ketoisophorone, both being compounds of great interest within the flavour and fragrance industry⁷⁷. Besides the previously known enzymes *Cgl*UPO and *Aae*UPO, also a novel UPO (*Hin*UPO) derived from *Humicola insolens* was utilised. In contrast to *Aae*UPO, both *Cgl*UPO and *Hin*UPO catalysed the selective hydroxylation at 4' position leading to 4-hydroxyisophorone and its further oxidised product 4-ketoisophorone⁷⁷. Subtle differences between the enzymes regarding stereoselectivity of alcohol formation and amount of over-oxidation were observed⁷⁷. Using a similar, broad UPO panel the conversion of the terpene derivative α -ionone and related compounds, which are commonly found aroma compounds in various species was investigated⁷⁸. *Aae*UPO was found to convert α -ionone (Figure 5) nearly selectively (92 % of total products) to its corresponding alcohol in 3'-position⁷⁸. Generally, in case of nearly all tested substrates and enzymes, multiple oxyfunctionalisation and overoxidation events occurred, therefore lacking desired selectivities. With respect to chemically activated sp³ C-H bonds *Aae*UPO has been challenged for the conversion of various alkylbenzene substrates (Figure 5)⁷⁹. The testing of a homologous row of *n*-alkylbenzenes ranging from ethylbenzene to pentylbenzene revealed a strong negative correlation of benzylic alcohol product formation and alkyl chain length, dropping from high TONs of 10.600 (ethyl) to 900 (pentyl)⁷⁹. In the case of ethylbenzene and propylbenzene, high enantioselectivities (>99 %) of the formation of the benzylic (R)-alcohol enantiomer were observed, rendering these reactions extremely interesting for application, since they proceed with high substrate conversions as well. This observation holds also true when the cycloalkylbenzenes tetrahydronaphthalene and indane (Figure 5) were tested. Both substrates are efficiently converted by *Aae*UPO (8600 and 9400 TON), reaching high *ee* values for both alcohol products, respectively (R)-indanol (87 %) and (R)-tetrahydronaphthol (>99%)⁷⁹. These benzylic hydroxylation reactions have become a blueprint reaction panel for subsequent upscaling and application-oriented UPO research utilising *Aae*UPO, since they combine high substrate conversions with high regio-, chemo- and stereoselectivity of alcohol formation.

1.2.2.3 Epoxidation of carbon-carbon double bonds

Another major class of UPO catalysed reactions are the epoxidation of carbon-carbon double bonds which are a common motif in natural and synthetic compounds. Besides their widespread occurrence they also constitute highly valuable intermediates in chemical synthesis. Epoxides

exhibit a considerable ring strain and are susceptible to nucleophilic attacks⁸⁰. Utilising this underlying principle, a plethora of valuable ring-opening products can be assessed, amongst others β -amino alcohols⁸¹, tetrahydrobenzofuranes⁸² and 1,2-diols⁸³. The installation of an arene epoxide intermediate catalysed by an UPO, which was further exploited to access a multitude of di-substituted cyclohexadienes by subsequent nucleophilic attack⁵⁴, has been discussed before (section 1.2.2.1).

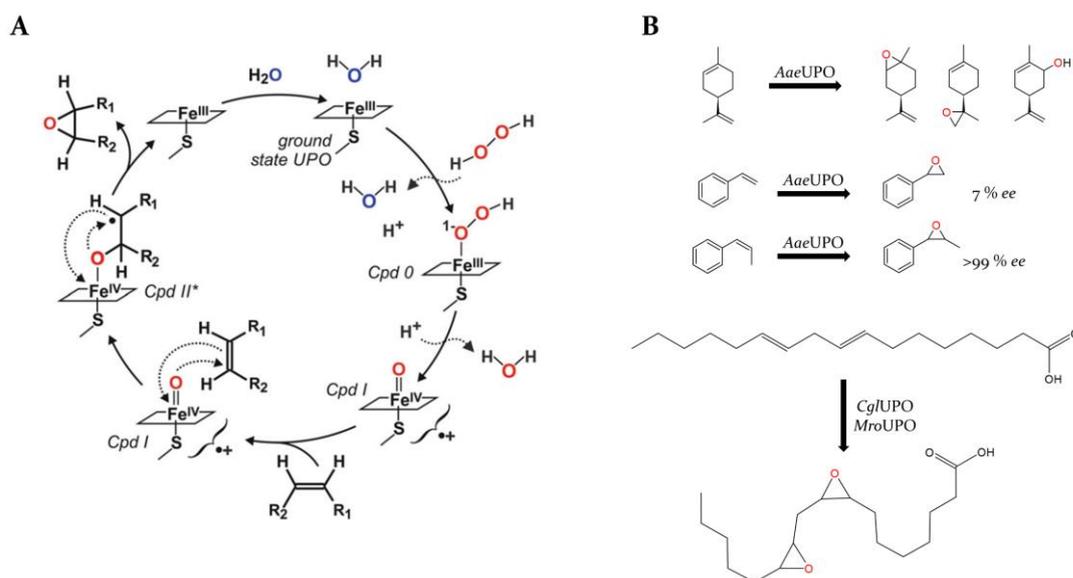

Figure 6: (A) Proposed mechanism of UPO catalysed epoxidation adapted from Hofrichter *et al.*⁵⁰ and selection of reported carbon double bond transformations (B)

The proposed catalytic cycle of epoxidation⁵⁰ (Figure 6 A) is nearly congruent to the classical two-electron transfer peroxygenase cycle (Figure 1A). The proposed discrepancy lies solely in the formation of an intermediate Compound II*, in which case the substrate remains linked to the iron-oxo species (Cys-S-Fe⁴⁺-O-R). Within the classical cycle, compound II (Cys-S-Fe⁴⁺-OH) is formed and facilitates a fast radical rebound of the generated substrate alkyl radical as could be observed in radical clock experiments³⁸.

An extensive, diverse set of cyclic and linear alkene substrates have been initially investigated for conversion by AaeUPO in 2013⁸⁴. AaeUPO proved to be an efficient catalyst for conversion of this broad panel of alkenes and some general hypothesis could be derived from the obtained experimental data. In the case of short, allylically substituted alkenes (2-methyl-2-butene, 2,3-dimethyl-2-butene, *trans*-2-butene, *cis*-2-butene, 2-methylpropene) exclusively the corresponding epoxide product was formed⁸⁴. On the contrary, when using linear alkenes (1-butene to 1-octene) product mixtures of epoxide and allylic hydroxylation products in varying amounts were obtained⁸⁴. This observation was also consistent when testing a variety of cyclic alkenes, including (*R*)-limonene (Figure 6B), leading up to three distinct epoxidation or allylic hydroxylation products, respectively. In a subsequent study styrene and methylated derivatives were tested for epoxidation by AaeUPO⁷⁹. Except for *trans*- β -methyl styrene, in which case

predominantly terminal hydroxylation at the methyl group occurred, all substrates were efficiently converted to the respective epoxide products (7900 to 10.700 TON) (Figure 6B). Astonishing differences in stereoselectivity of the obtained epoxide products could be observed, ranging from negligible (styrene: 7 % *ee*), low (α -methyl styrene: 29 % *ee*) and absolute (*cis*- β -methyl styrene: >99 % *ee* 1*R*,2*S*-(+) epoxide). Taken together, these observations point towards a crucial effect of the methyl group in substrate positioning (stereoselectivity) as well as double bond epoxidation activity (*cis-trans*-isomerism)⁷⁹.

Another group of substrates recently attracting great industrial interest for UPO catalysed epoxidation are unsaturated fatty acids and their derivatives. Unsaturated fatty acids are an emerging attractive substrates in sustainable biocatalysis and chemistry, primarily due to their abundance in natural vegetable oils derived from a variety of relevant crops and therefore the consideration of being a renewable “green” source of valuable carbon compounds⁸⁵. The epoxidation products of unsaturated fatty acids are important building blocks in the synthesis of non-isocyanate polyurethanes⁸⁶, bolaamphiphiles for drug delivery⁸⁷ and diesters⁸⁸. In an initial study the two short-type peroxygenases *Cgl*UPO and *Mro*UPO were investigated towards the conversion of several mono-unsaturated fatty acids (C₁₄-C₂₂) and related compounds⁸⁹. Whereas the widely studied long-type UPOs *Aae*UPO and *Cci*UPO were not capable of epoxide formation, *Mro*UPO and *Cgl*UPO proved to be very suitable catalysts for this reaction. *Cgl*UPO being highly selective towards epoxide formation nearly throughout the substrate panel (C₁₄ to C₂₀: >91 % of epoxide product)⁸⁹. Also, fatty acid methyl esters and di-unsaturated fatty acids, such as linoleic acid (Figure 6B), were converted with high specificity to the corresponding mono- or di-epoxides by *Mro*UPO and *Cgl*UPO⁸⁹. In a follow-up study fatty acid epoxidation was investigated in-depth by utilising a broader enzyme panel (*Mro*UPO, *Cgl*UPO and *Hin*UPO) and natural vegetable oils as complex mixture and substrate pools of saturated-, mono- and polyunsaturated fatty acids⁹⁰. *Hin*UPO was found to be the only UPO out of the tested panel, that was capable of converting the tri-unsaturated substrate α -linolenic acid to its corresponding fatty acid tri-epoxide⁹⁰.

1.2.3.4 Further reaction types

Besides the reaction types that have been presented in detail within the previous section there are additional reaction types of high interest, that have been reported to be catalysed by UPOs (Figure 3). One of the initially described activities, also reflected by the first classification as “haloperoxidase”^{30,35} is the halogenation of aromatic compounds, which is analogous to the reactivity of the well-studied chloroperoxidase (CPO) from *Caldariomyces fumago*⁹¹. However, the specific activities for halogenation reactions catalysed by UPOs are reported to be approximately one order of magnitude lower when compared to CPO^{30,35}. Halogenation proceeds via the oxygenation of halide ions by compound I resulting in the corresponding highly

reactive intermediate hypohalous acids, which then lead to the unspecific halogenation of electron rich-substrates⁹².

A broad class of further UPO reactions attracting keen interest in the industrial sector are dealkylation reactions, which can be categorised as a specific case of hydroxylation reactions, as they proceed via formations of unstable hemiacetal and hemiaminal intermediates⁵⁰. These intermediates are then decaying towards the dealkylated product and a simultaneous formation of by-products⁹³. One already discussed example of C-dealkylation is the fatty acid shortening catalysed by *Mro*UPO (section 1.2.2.2), which proceeds via sequential hydroxylation and oxidation steps leading to the formation of unstable intermediates, finally resulting in the shortening of the alkyl chain and the release of carbon dioxide⁷. Another example of C-dealkylation is the side chain removal from corticosteroid substrates, which follows a similar sequential pattern and was described to be catalysed by *Mro*UPO and the closely related enzyme *Mwe*UPO (*Marasmius wettsteinii*)⁴⁷. O-dealkylation reactions of *Aae*UPO have been described in the scission process of non-phenolic lignin model dimers⁹⁴ and simple cyclic and linear ethers⁹⁵. The O-dealkylation of benzodioxole compounds, which is a highly specific activity of UPOs and has not been described for other enzyme classes so far, has been exploited for the development of a simple, colorimetric UPO activity assay. 5-nitro-1,3-benzodioxole (NBD) is converted by UPOs to the colorimetric compound 4-nitrocatechol (λ_{max} : 425 nm) and formic acid, therefore the conversion can be easily followed with the aid of a spectrophotometer⁹⁶. N-dealkylation, another common form of dealkylation reaction, was observed for *Aae*UPO when converting the medicinal drugs sildenafil, lidocaine and 4-dimethylaminoantipyrine⁶⁴. *Mro*UPO has been reported to be a suitable catalyst for the selective N-desmethylation of the bile acid reabsorption inhibitor SAR548304⁹⁷.

Another remarkable UPO reactivity is the efficient oxidation of organic compounds at heteroatoms, namely nitrogen and sulfur. The first description of this reactivity dates to 2008, utilising pyridine and ring-substituted derivatives, which are converted by *Aae*UPO to their respective N-oxides⁹⁸. Subsequent reports using *Aae*UPO and *Cra*UPO reported on the conversion of the aromatic heterocycle dibenzothiophene to a complex product mixture, including the heteroatom oxidation products dibenzothiophene-sulfoxide and -sulfone⁵⁷. A panel of ring-substituted aryl alkyl sulfides was shown to be efficiently converted by *Aae*UPO yielding the corresponding chiral sulfoxides, thereby reaching overall high conversions and enantiomeric excess (up to >99%) throughout the nearly complete panel⁹⁹.

1.2.3 Prospective and challenges

Despite their relatively young history, UPOs have rapidly developed into a new rising enzyme class within the field of biocatalysis, bearing great potential as highly active and promiscuous C–H oxyfunctionalisation catalysts. Recent review articles state UPOs to be “*en route* to becoming dream catalysts”¹⁰⁰ and “swiss army knives for oxyfunctionalisation chemistry”⁵². Due

to the various analogies, namely being heme-thiolate enzymes, the catalysed reaction portfolio and the reaction cycle, that reassembles the peroxide shunt pathway⁴², UPOs are often compared to the well-known class of cytochrome P₄₅₀ (CYPs) enzymes.

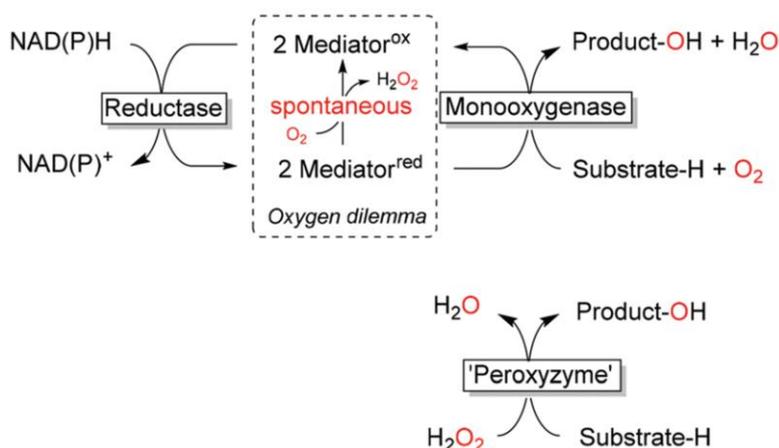

Figure 7: Schematic comparison of catalysis and redox equivalent requirement of CYP monooxygenases and peroxygenases adapted from Burek *et al.*¹⁰¹

When comparing both enzyme classes, arguably the two most beneficial features of UPOs are their occurrence as stable glycosylated monomeric or homo-dimeric, secreted enzymes and the sole dependence on hydrogen peroxide as pre-reduced oxygen source. Peroxygenases have been reported to be highly stable and active in a variety of organic solvents³⁸ and are reported to be applicable even under non-aqueous neat conditions^{102,103}. CYPs are a highly heterogeneous class of enzymes, which are often parts of complex protein networks, relying on associated reductase and accessory protein for shuttling reduction equivalents to the oxygenase domain^{104,105}. In their simplest form, CYPs are occurring as self-sufficient, monomeric fusion proteins composed of a fusion of reductase and oxygenase domain, as in the case of the well-studied CYPs BM₃¹⁰⁶ (*Bacillus megaterium*) and CYP_{116B}¹⁰⁷ (*Tepidiphilus thermophilus*).

The comparison of the reducing networks of both enzymes (Figure 7) exhibits great differences. CYPs are dependent on the shuttling of redox equivalents originally derived from NAD(P)H, mostly transported from flavine adenine dinucleotide (FAD) through flavin mononucleotide (FMN) and intra- or intermolecular routes to ultimately reduce molecular oxygen within the oxygenase unit¹⁰⁸. Routes of transport and the involved reductase proteins vary greatly depending on the species, including iron-sulfur proteins in many bacteria and archaea⁴². However, throughout the consecutive transport of the two hydride ions, side-reactions with molecular oxygen can occur (Figure 7), a process coined as “oxygen dilemma”¹⁰⁹ leading to the formation of hydrogen peroxide. This process, commonly known as “uncoupling” additionally to the occurring loss of precious reduction equivalents needed for substrate turnover, can further damage the protein considerably due to the formation of reactive oxygen species (hydrogen peroxide). Recent work suggests that the amount of uncoupling is strongly

dependent on the nature of the substrate, whereas in the case of a natural substrates nearly all consumed NAD(P)Hequivalents are reflected in product formation (2% uncoupling), unnatural substrates can lead to a nearly complete loss of the equivalents (93 %) before substrate turnover¹¹⁰. UPOs on the other hand are considered rather simple catalysts solely relying on pre-reduced hydrogen peroxide as oxygen source (Figure 7), thereby neglecting complex transport chains and the use of expensive reduction equivalents, which in the case of CYP enzymes are in most cases recycled by enzymatic *in situ* cascades¹¹¹ to allow for economically feasible processes. H₂O₂ is heterolytically cleaved by the action of the conserved catalytic glutamate residue resulting in compound I formation (Figure 2) and associated base catalyst.

Astonishingly this UPO/CPO specific principle of acid-catalysed hydrogen peroxide activation has recently been successfully transferred to convert CYP enzymes into artificial peroxygenases. Using dual functional molecules (DFM) as additives, which are acting as anchoring molecules as well as general acid-base catalyst via an imidazole moiety for hydrogen peroxide cleavage, CYP BM₃ could be transformed into an artificial peroxygenase capable of sulfoxidation and styrene epoxidation¹¹². The principle of CYP DFM peroxygenase mimics could be further exploited in the *O*-demethylation of aromatic ethers¹¹³, aromatic hydroxylation of naphthalene¹¹⁴ and hydroxylation of short, linear alkanes¹¹⁵. However, the obtained catalytic parameters (TONs, TOFs) of the artificial peroxygenase systems are considerably lower when compared to *Aae*UPO^{31,38,55,95}.

Hydrogen peroxide plays a Janus role in the catalysis of unspecific peroxygenases. While being indispensable for enzymatic activity as co-substrate, high concentrations of hydrogen peroxide can also rapidly inactivate the enzyme. In 2016 UPOs have been firstly describe to possess pronounced catalase activity, thereby converting hydrogen peroxide under release of water and oxygen¹¹⁶.

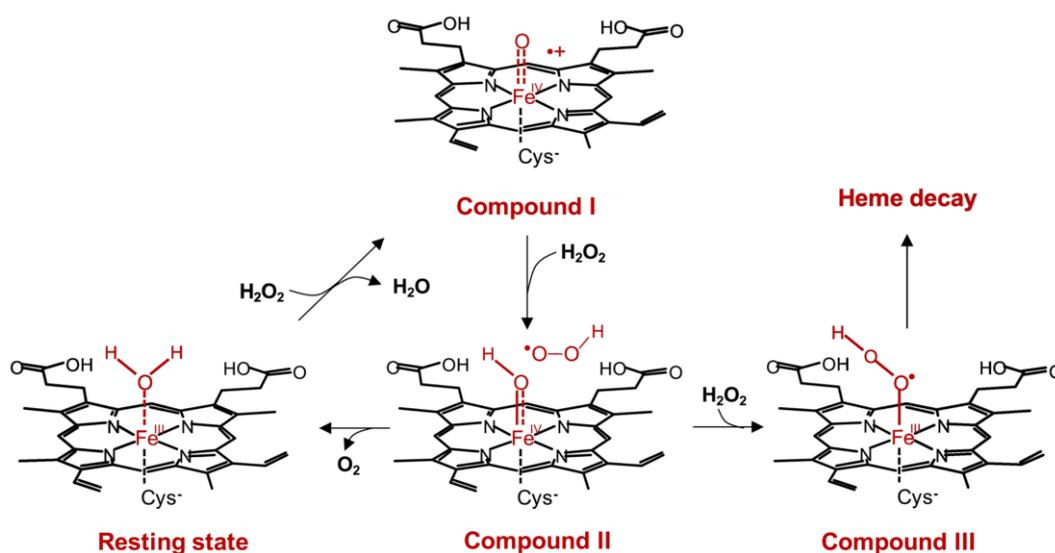

Figure 8: Formation of Compound III and subsequent heme decay in UPOs adapted from Aranda *et al.*¹¹⁷

Excess hydrogen peroxide, especially in the absence of a further substrate for hydroxylation has been described to lead to the binding of a second H₂O₂ molecule to the intermediate compound II resulting in formation of compound III (Figure 8)¹¹⁶. The subsequent reaction of compound III with another H₂O₂ molecule is believed to cause rapid oxidative damaging of the prosthetic heme group (bleaching) and surrounding amino acids, based on a Haber-Weiss decomposition reaction leading to highly reactive hydroxyl radicals^{101,116}. The observation, that by adding a sufficient amount of suitable substrate for UPO conversion the catalase activity can be greatly diminished, highlights the possibility and requirement of reaction condition fine-tuning to achieve maximal substrate conversion, while minimising oxidative damage of the enzyme¹¹⁶.

Numerous approaches to overcome H₂O₂-caused UPO inactivation and thereby maximizing the catalytic performance of UPOs have been reported in recent years. These versatile H₂O₂-generating systems encompass sophisticated physicochemical and electrochemical methodologies up to enzymatic *in situ* cascades. However, they underly the general concept of continuously supplying a defined, controllable amount of H₂O₂, thereby constantly fuelling the UPO over time, while keeping an overall low local hydrogen peroxide concentration to minimise oxidative damage. Depending on the respective substrate and enzyme a certain “sweet spot” for every supply setup needs to be established prior to achieve optimal catalytic performance reaction. First reports using a simple dosing setup with a syringe pump and *in situ* production by a glucose oxidase were already described in 2008 and 2004, respectively^{30,98}. In recent years, highly sophisticated methods have been developed to generate a continuous on demand supply of H₂O₂. From a physical chemistry standpoint, most notably are the utilisation of atomic waste for water splitting¹¹⁸, plasma^{119,120} and the reduction of O₂ through bismuth oxychloride by the application of ultrasound¹²¹.

Another major focus has been the use of diverse photo- and electrochemical systems. First reports of photochemical hydrogen peroxide supply for UPO in 2011 utilised FMN for the reduction of molecular oxygen¹²². Subsequent work employed inorganic photocatalysts, including gold-loaded titanium dioxide^{123,124}, gold-palladium nanoparticles¹²⁵, pure titanium dioxide¹²⁶, photovoltaic-photoelectrical tandem cells¹²⁷ and graphitic carbon nitride¹²⁸. Follow up work on the use of biologically occurring photosensitizers such as FMN has led to the successful implementation of sodium anthraquinone sulfonate¹²⁹ and various acridine derivatives¹³⁰ for hydrogen peroxide production.

Arguably the most promising and challenging supply systems have been constructed by the means of enzyme-based circuits. These cascades employ diverse oxidase enzymes, which typically convert their natural substrate using molecular oxygen, leading to the release of the corresponding product and hydrogen peroxide as by-product. The utilisation of glucose oxidase as H₂O₂ supply system is widespread, due to the commercial availability as inexpensive biocatalyst (from *Aspergillus niger*) and has also been the first described *in situ* supply systems

for UPO catalysis^{30,98}. However, the atom efficiency of the reaction is relatively poor, since solely 2 out of all possible 24 electrons of a glucose molecule can be exploited for the reduction and also the accumulation of gluconolactone as by-product occurs³¹. More complex systems have been developed in recent years, using methanol as sacrificial electron donor, and promoting complete oxidation to yield CO₂ and three equivalents H₂O₂ per molecule of methanol. By construction of a four-enzyme cascade, namely an alcohol oxidase (*Pichia pastoris*), formaldehyde dismutase (*Pseudomonas putida*), formate dehydrogenase (*Candida boidinii*) and a NAD⁺ recycling enzyme (*Rhodococcus jostii*) astonishing turnover numbers of almost 30000 for the benzylic hydroxylation of ethylbenzene (Figure 5) by *Aae*UPO could be achieved, being the highest values for any UPO catalysed reaction reported to date³¹. Subsequently, promising simplified one-enzyme solutions for H₂O₂ generation have been developed, namely by utilising choline oxidase^{132,133} (*Arthrobacter nicotianae*), sulfite oxidase¹³⁴ (*Arabidopsis thaliana*), formate oxidase^{135,136} (*Aspergillus oryzae*) and a hydrogenase¹³⁷ (*Ralstonia eutropha*) coupled flavin photosensitizer. A slightly altered approach has been recently reported using a recombinantly produced cascade comprising a dual functional fusion-protein, consisting of an aryl alcohol oxidase for H₂O₂ supply and a peroxygenase¹³⁸.

The optimisation of process stability is of outstanding interest to steer UPO towards application in the industrial sector, in which case high activities and substrate loading and turnover are a prerequisite for potential implementation in the (chemo)enzymatic synthesis of fine chemicals. Besides the design of smart and efficient H₂O₂ supply systems, which is a crucial point towards application due to the described detrimental UPO inactivation by hydrogen peroxide¹¹⁶, already occurring in low mM range, other factors have been shown to enhance the process stability of UPOs. One beneficial factor can be rational design and monitoring of UPO batch processes based on modelling and simulation, which has been recently described¹³⁹. This approach aids the understanding of the occurring reaction mechanism and how to balance productive transformations (hydroxylation) and catalase malfunction (inactivation) at an optimal rate. Another classical factor concerning stability is the utilisation of immobilised enzymes for catalysis, which can enhance enzyme stability and furthermore enables to recycle the enzyme to perform subsequent reaction cycles. Immobilisation procedures have been successfully applied for *Aae*UPO using a metal-affinity binding tag¹⁴⁰, poly(methyl methacrylate)resins¹²⁴, covalent disulfide linkage to Thiol-Sepharose¹⁴¹ and PVA/PEG gels and hollow fibers¹⁴². The described strategies resulted in a substantial improve in TON when compared to the free enzyme (60x fold)¹⁴² and also minimised oxidative inactivation of the UPO by the photocatalyst¹²⁴ based on the spatial separation.

Immobilised UPOs can furthermore be readily applied for substrate conversion under non-aqueous, neat conditions, additionally exploiting the solvent as substrate reservoir. A first promising approach was reported for the conversion of ethylbenzene under neat conditions by

a resin immobilised *Aae*UPO, which could be further upscaled to a preparative scale yielding 1.3 g of enantiomerically pure (*R*)-phenylethanol¹⁰². The immobilisation of *Aae*UPO on Immobeads enabled the efficient epoxidation of a diverse substrate panel under neat conditions¹⁰³. A recent approach could transfer this concept to the hydroxylation of cyclohexane under neat conditions, using *Aae*UPO embedded in alginate beads¹⁴³.

The high substrate promiscuity of UPO, while being a driving force of the extraordinary potential of this enzyme class can also be considered a major drawback of current UPO catalysis.

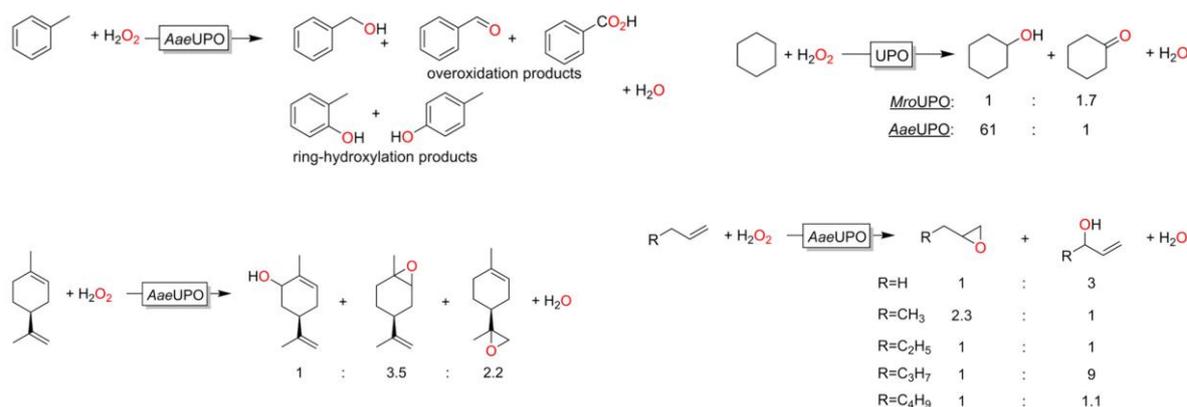

Figure 9: Selectivity issues of UPO catalysis adapted from Hobisch *et al.*⁵²

Depending on the structure of the substrate, diverse product mixtures (Figure 9) are obtained as already discussed in the case of benzene⁵⁶, cyclohexane⁶⁸, limonene and linear alkene epoxidation⁸⁴. A similar pattern can be observed regarding the conversion of toluene by *Aae*UPO (Figure 5), leading to the formation of at least 5 reaction products¹⁴⁴. Recently, peroxygenases have therefore been described to be “more enantio- than regioselective”⁵². Only a few conversions are currently known to combine high substrate turnover with high regio- and stereoselectivities (>99 % *ee*), namely the conversion of ethylbenzene yielding (*R*)-phenylethanol⁷⁹, the epoxidation of *cis*- β -methyl styrene⁷⁹ and the hydroxylation of tetrahydronaphthalene⁷⁹. Therefore, these conversions have become popular showcase reactivities of UPO catalysis in recent years. Especially ethylbenzene and *cis*- β -methyl styrene have been extensively exploited as model substrates in all previously reported photocatalytic^{122,124,126–130} and enzymatic^{131–137} hydrogen peroxide supply systems for UPO catalysis.

These shortcomings are often addressed within the field of biocatalysis by the expansion of the panel of respective enzymes within a class. This principle is amongst others known in the case of alcohol dehydrogenases (ADHs)¹⁴⁵ and imine reductases (IREDs)¹⁴⁶, creating a broad panel of enzymes active on different core structures and yielding contrary product stereoisomers. The availability of a broad defined enzyme panel greatly enhances its applicability throughout all research areas, as it allows for example organic chemists to employ a tailored enzyme for a specific chemical conversion.

UPO genes are to date known to be exclusively occurring within the fungal kingdom and *Peronosporomycetes*, being widely spread throughout all realms of the kingdom, apart from true and fission yeast (*Saccharomycotina*; *Schizosaccharomycetes*)⁵⁰. Recent studies annotate approximately 4500 unique short- and long-type UPO sequences derived from roughly 1100 fungal genomes⁵⁰. Relatively to the high abundance of putative sequences, the number of reported enzyme products, currently 11 produced and at least partially characterised wild type enzymes, is severely limited^{50,78,147}.

1.2.4 Heterologous production and directed evolution campaigns

The substantial limitation of accessible peroxygenase enzymes arises primarily through their challenging heterologous production, caused by the occurrence as post-translationally modified enzymes, exhibiting substantial glycosylation patterns and disulfide linkages^{52,100,148}. Initial reports on UPOs utilised homologously produced wild type enzymes, produced by the respective fungal strain in a bioreactor setups over the course of 2-3 weeks^{30,35,46}. Specific yields for *Aae*UPO, *Cra*UPO, *Cgl*UPO and *Mro*UPO of 9 mg/L³⁰, 19 mg/L³⁵, 40 mg/L⁴⁸ and 445 mg/L⁴⁶, respectively, have been reported. In addition to the time-consuming production, only the respective wild type enzyme can be produced, and the overall recovery of pure protein after several purification steps are reported to be below 20 %^{30,35,46}.

The production of UPOs in a heterologous production host can enable targeted modifications, including the attachment of purification and detection peptide tags and the alteration of amino acid residues by means of mutagenesis to alter enzyme properties. In 2013, using an industrial strain of the ascomycetous mould *Aspergillus oryzae* as host, the first heterologously produced UPO derived from *Coprinopsis cinerea* was reported⁷⁰. In the following year, the creation of a secretion variant of *Aae*UPO, coined PaDa-I was reported, harbouring nine amino acid exchanges in comparison the wild type enzyme and yielding recombinant titres of 8 mg/L in the yeast *Saccharomyces cerevisiae*¹⁴⁹. The heterologous production yield of this secretion variant could be further increased to 217 mg/L by using the methylotrophic yeast *Pichia pastoris* (syn. *Komagataella phaffii*) as heterologous host in a bioreactor setup¹⁵⁰. In recent years, the first successful production setups of three peroxygenases in the prokaryotic standard host *Escherichia coli* have been reported. This panel of recombinant UPOs consists of the short-type UPOs *Mro*UPO, *Cvi*UPO and *Dca*UPO^{49,151}. For *Cvi*UPO and *Dca*UPO, recombinant production titres of 7 and 2.8 mg/L, respectively, have been reported⁴⁹.

By the transfer to standard laboratory hosts as *E. coli*, *S. cerevisiae* and *P. pastoris* fulfilling crucial general features as short-doubling times, inexpensive media formulations, high transformation efficiencies and straightforward genetic manipulation, UPOs have gained a substantial increase in interest throughout recent years^{52,100,117,148}. This hypothesis is further reflected by the observation that all previously discussed *in situ* hydrogen peroxide systems (see chapter 1.2.3) were constructed using the secretion variant PaDa-I as default enzyme, which can

be produced by inexpensive and time saving fermentation of *P. pastoris* using established protocols^{126,149,150}. One way to efficiently exploit heterologous hosts is the tailoring of UPOs towards desirable traits by mimicking natural evolution on a laboratory scale within a processed coined “directed evolution”¹⁵². Directed evolution has developed into an extremely powerful tool for the improvement of various protein traits leading to a plethora of successful campaigns, including enhanced solvent stability^{153,154}, thermostability^{155,156}, activity^{157–159}, regio- and stereoselectivity^{73–75} and even unlocking new to nature chemistry^{160–162}. This continuous success story culminated in 2018, when the Nobel prize for Chemistry was awarded to Frances H. Arnold, who pioneered the principle of directed evolution.

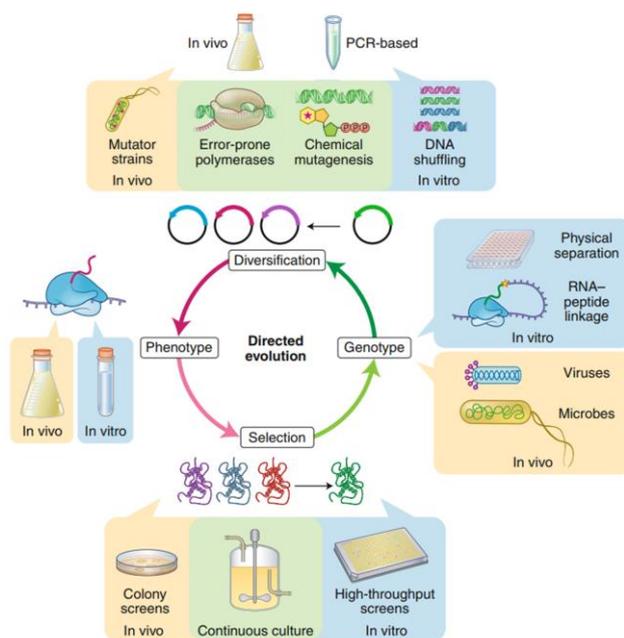

Figure 10: Schematic overview of a general workflow of directed evolution adapted from Morrison *et al.*¹⁶³

The general workflow of a classical directed evolution approach (Figure 10) starts with the diversification of a target gene by means of targeted site saturation mutagenesis¹⁶⁴ (codon degeneracy) or random mutagenesis through error prone PCR¹⁶⁵ or random shuffling of gene sequences (DNA shuffling)¹⁶⁶. Respective enzyme variants are produced by a heterologous host within a colony screening or 96/364 well plate liquid screening setup and the resulting phenotype (enzyme) assessed under application of evolutionary pressure to identify variants exhibiting desired improvements. The genotype of improved variants can be recovered, identified and used as new genetic template for further rounds of diversification, starting the cycle of directed evolution once again (Figure 10). The cycle can be in theory repeated indefinitely, but is in general repeated until the evolved enzyme characteristics comply with the goals of the directed evolution campaign and no further significant improvements can be determined.

Regarding UPOs several examples of successful directed evolution campaigns exist. The first described heterologously assessed UPO, *CciUPO*⁷⁰, has been produced utilising *Aspergillus oryzae*— an organism commonly used as host in industrial setups due to high secretion capacities. However, to date this organism is not amendable for high-throughput requiring directed evolution approaches due to low transformation efficiencies and the lack of episomal plasmid systems⁶⁷. The development of the *AaeUPO* secretion variant PaDa-I (syn. *AaeUPO*^{*}) is a prime example for an extensive directed evolution campaign, screening more than 9000 clones towards secretion improvement using the yeast model organism *S. cerevisiae* as host and achieving a 3250-fold overall activity improvement¹⁴⁹. The final variant of the campaign, PaDa-I, accumulated a total of nine amino acid exchanges compared to the full length wild type enzyme¹⁴⁹. Four (F12Y, A14V, R15G, A21D) out of these nine mutations are located within the native signal peptide (43 amino acid) that guides secretion, improving the secretion of the wild type enzyme by a factor of 27 and therefore pointing towards a crucial influence of the primary sequence on the secretion in the heterologous host *S. cerevisiae*¹⁴⁹. The reason for an approximately 120-fold activity increase due to the five mutations (V57A, L67F, V75I, I248V, F311L) introduced in the mature protein remained more elusive¹⁴⁹. A rationalisation was attempted based on the successful crystallisation of PaDa-I in 2018¹⁶⁸. Mutations V57A and L67F are believed to preserve the natural N-terminus of the mature protein (EPGLPPPGPL) when produced in *S. cerevisiae* and *P. pastoris*¹⁶⁸, whereas in the case of the *Agrocybe aegerita* wild type enzyme, N-terminal proteolysis (EPG↓LPPPGPL) occurs³⁶. While the substitutions V75I and I248V lead to no substantial structural alterations, the F311L exchange widens the heme entrance channel shaped by the residues F191 and F76 from 4.1 in the wild type enzyme³⁶ to 7.8 Å through interactions of the aromatic side chains with residue 311¹⁶⁸.

The secretion variant PaDa-I has been the departure point for various subsequent directed evolution campaigns. Firstly, a UPO variant (JaWa) for the enhanced synthesis of 1-naphthol from naphthalene was evolved, exhibiting two additional substitutions (G241D and R257K) leading to a 1.5-fold increased catalytic activity towards naphthalene when compared to the PaDa-I predecessor¹⁶⁹. Employing the surrogate peroxidase (ABTS) and peroxygenase (NBD) assays, the ratio of unwanted peroxidase to desired peroxygenase activity (see chapter 1.2.2.1) could be shifted by a factor of up to 4 through the introduction of three additional exchanges (T120V, S226G, T320R) to PaDa-I¹⁷⁰. Through the application of low mutational loads and less stringent selection procedures—a principle coined “neutral drift”¹⁷¹, a panel of 25 variants originating from PaDa-I was selected and tested, leading to the identification of variants with beneficial activities, solvent and thermal stabilities^{172,173}. Based on the previously reported capability of *AaeUPO* to convert the β -blocker propranolol to the HDM 5'-hydroxypropranolol⁶² and by selecting the previously obtained JaWa variant¹⁶⁹ as starting point, a directed evolution campaign was conducted¹⁷⁴. Through the introduction of an additional substitution (F191S) to

the JaWa variant and application of an enzymatic *in situ* hydrogen peroxide supply system¹³¹, outstanding TTNs of 224.000 in combination with high regioselectivity (99 %) were achieved¹⁷⁴. Recently, a mutagenesis study of the F191 and F76 residues of PaDa-I has been reported, which are crucial for channel geometry and substrate positioning¹⁶⁸, to assess the influence of both residues on catalytic properties¹⁷⁵. Previously engineered variants have further been applied to benchmark their suitability in the synthesis of various HDMS¹⁷⁶.

With the aid of the established prokaryotic *E. coli* production system, enzyme variants of *Mro*UPO and *Cvi*UPO have been created and characterised^{147,151}. In contrast to the previously introduced *S. cerevisiae* UPO production setup^{149,169,174} high-throughput capacity is not apparent and recombinant enzyme yields are comparably low⁴⁹, thereby currently impeding directed evolution approaches. Based on the results of a previous study⁸⁹, but utilising recombinantly produced *Mro*UPO, single and double substituted heme channel variants were produced and characterised regarding the conversion of unsaturated fatty acids to their corresponding epoxide and alcohol/ketone products¹⁵¹. Through the introduction of two phenylalanine residues (I153F, S156F) within the heme access channel, the epoxidation of oleic acid could be completely abolished, while preserving hydroxylation activity at the subterminal ω -1 position¹⁵¹. In a follow up study this switch in preference, mimicking the natural reactivity profile of *Aae*UPO, has been further rationalised by means of molecular dynamic simulations¹⁷⁷. The introduction of the two aromatic side chains of I153F and S156F alters the aliphatic amino acid composition of the access channel towards a long-type UPO typical composition, which are characterised by the predominant occurrence of rigid, aromatic side chains^{36,168}. A similar study on the selectivity of fatty acid epoxidation of oleic and linoleic acid was performed using *Cvi*UPO as recombinantly produced target enzyme¹⁴⁷. Two single substitution variants (F88L, T158F) were generated to mimic the active site geometry of *Cgl*UPO, which has previously been described to possess high activities and specificities for epoxide formation⁸⁹. Catalytic parameters and selectivities of the two variants proved to be inferior to the data obtained with wild type *Cgl*UPO⁸⁹, which has been reported to be not producible via the prokaryotic *E. coli* system^{49,147}.

1.3 Protein secretion in yeast

Arguably the most successful system for UPO production and subsequent high-throughput amendable protein engineering has been established in *S. cerevisiae* yielding the secretion variant PaDa-I⁴⁹ and multiple substrate engineered offspring variants^{169,172,174,176}. Baker yeast (*S. cerevisiae*) ranks amongst the most studied organisms in biological research, rendering it a model eukaryotic model system. As a common production host for recombinant proteins *S. cerevisiae* has been employed since decades¹⁷⁸⁻¹⁸⁰, benefiting from cheap media formulations, the possibility of post-translational modifications including glycosylation and disulfide-linkage, high transformation efficiencies and a versatile toolbox of regulatory elements, selection

markers and plasmids for target gene expression. Especially the capability of target protein secretion into the cultivation media renders yeasts a highly valuable production hosts on an industrial scale since the protein can be obtained already enriched within the supernatant due to the rather low amount of naturally secreted enzymes and further omitting cost-intensive cell lysis procedures for recovery^{179,180}. Major biopharmaceutical products produced by *S. cerevisiae* include insulin, hepatitis vaccines and human serum albumin¹⁸¹.

Protein secretion in *S. cerevisiae* and methylotrophic yeast of great industrial interest such as *Pichia pastoris* (syn. *Komagataella phaffii*) and *Hansenula polymorpha* (syn. *Ogataea angusta*) follows a similar pattern of cellular mechanisms¹⁸².

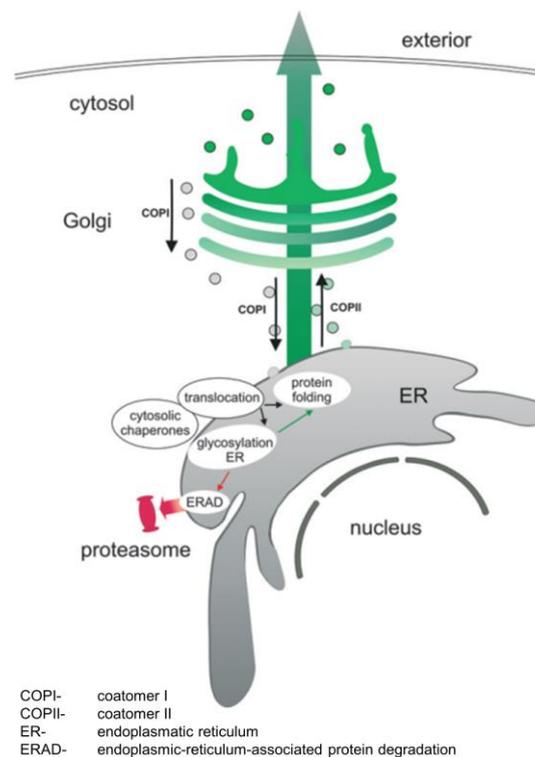

Figure 11: Schematic overview of canonical protein secretion in yeasts adapted from Delic *et al.*¹⁸²

Protein secretion in yeast (Figure 11) constitutes a complex multi-level process that shall be discussed in brief. Starting with the recognition of the N-terminally located signal peptide of a protein by a signal-recognition particle (SRP) and subsequent interaction with an SRP receptor, the nascent polypeptide is co-translationally translocated into the endoplasmic reticulum (ER)¹⁸³. Within the ER the signal peptide is cleaved of the polypeptide by action of a signal peptidase complex^{182,183}. Following translocation, the N- (Asp) and O- (serine) linked glycosylation occurs through the consecutive action of multiple oligosaccharyltransferase enzymes¹⁸³. Overall glycan compositions can vary between different yeast species, but naturally yeast primarily attach high mannose glycan structures to asparagine residues of a secreted protein^{184,185}. After occurring glycosylation, the protein undergoes several chaperone aided folding and disulfide-linkage steps¹⁸², which in case of misfolding lead to proteasome assisted

protein degradation by activation of an unfolded protein response¹⁸⁶. Correctly folded proteins are then transported from the ER to the *cis*-Golgi engulfed in COP II vesicles¹⁸². Within the Golgi apparatus glycan structures are further modified through terminal trimming and further branching^{182,183}. The process of secretion is completed by the transport of correctly processed proteins within secretory vesicles and the final release from the cell via exocytosis^{182,186}.

One crucial factor within the secretion process is the attachment of a suitable signal peptide, which primes the protein for subsequent secretion through the interaction with SRP and a suitable receptor, leading to ER translocation of the polypeptide (Figure 11). Signal peptide sequence alteration proved to be a vital factor in the directed evolution campaign of *AaeUPO*, as highlighted by a 27-fold secretion increase of the wild type *AaeUPO* enzyme in *Saccharomyces cerevisiae* by the introduction of four substitutions within the native 43 residue signal peptide¹⁴⁹. Signal peptides are ubiquitously occurring, N-terminally attached peptides in a variety of prokaryotic and eukaryotic species, which regulate the trafficking of proteins to defined cellular compartments and shuttle proteins into the secretory pathway¹⁸⁷. In most cases, signal peptides exhibit a length of 20 to 30 amino acids and are consisting of three distinct domains, namely a basic N-terminal domain, a hydrophobic core region and a slightly polar C-terminal domain¹⁸⁸. Amino acid composition and length are crucial factors regarding the interaction with respective translocon complexes¹⁸⁹, subsequent protein maturation and glycosylation^{190,191}.

For the targeted secretion of heterologous proteins in the two most common yeast expression hosts *S. cerevisiae* and *P. pastoris* in the majority of cases a 87 amino acid signal peptide coined “ α factor prepro leader” is utilised^{186,192,193}, which is originally derived from the secreted α mating factor of *S. cerevisiae*. Owing its popularity, several directed evolution campaigns have been conducted to engineer the α factor prepro leader for enhanced secretion of antibodies¹⁹⁴, interleukin 2¹⁹⁴ and laccases¹⁹⁵⁻¹⁹⁷. Further examples of signal peptide targeted directed evolution approaches include the aforementioned evolution of PaDa-I¹⁴⁹ and aryl alcohol oxidases^{198,199}. While substantial efforts have been undertaken to develop universally optimised α factor prepro leader derivatives^{197,200}, suitability is strongly depending on the attached protein for secretion, as PaDa-I for example cannot be efficiently secreted when using α factor prepro leader instead of the evolved, natural signal peptide¹⁴⁹.

Besides the model eukaryotic organism *S. cerevisiae*, the methylotrophic yeast *P. pastoris* has gained substantial interest within the last decades²⁰¹⁻²⁰⁵, being a popular host to produce recombinant proteins within industrial settings. In contrast to *S. cerevisiae*, *P. pastoris* is a Crabtree-negative yeast²⁰⁶, thereby enabling extraordinary high cell densities and recombinant protein titres within fermentation setups. In recent years a steadily growing toolbox of valuable synthetic biology parts such as modular circuits²⁰⁷, strong as well as tightly regulated promoters^{208,209} and signal peptides²¹⁰ has become available. Especially promoter elements which are derived from genes involved in the specialised methanol utilization (MUT) pathway²¹¹ are

popular, which is a core metabolic feature of methylotrophic yeasts. The widespread application of these promoters is based on their common tight repression and strong methanol induction profile^{208,209,211}. Besides this sharp repression versus induction profile, several novel MUT promoters with altered profiles have been described in recent years, enabling methanol-free derepressed gene expression upon primary carbon source depletion^{208,212}. Derepressed gene expression is of high interest, as methanol bears drawbacks as inducer during large-scale fermentations as toxic and flammable agent. Recent studies describe orthologous MUT promoter elements originating from the methylotrophic yeast *Hansenula polymorpha*, which exhibit pronounced derepression profiles and outperform endogenous, strong *P. pastoris* MUT promoters for target protein production^{213,214}.

1.4 Modular cloning systems

The emergence of the field of synthetic biology throughout the past decades^{215,216} has been accompanied by the development of numeral cloning systems allowing for the rapid and efficient construction of complex circuits. One widely used system constitutes Golden Gate cloning, which basic design principles have been introduced in 2009²¹⁷. Golden Gate cloning relies on the utilization of Type II s restriction enzymes, commonly BsaI, BbsI, BsmBI, which are characterised by their ability to cut double stranded DNA adjacent to their recognition sequence, thereby creating 4 bp sticky overhangs²¹⁷. Since the Type II s recognition sites are released from the cloning fragments upon digestion, the cloning can be performed simultaneously with DNA ligation in a simple one pot-one step manner and the programmable 4 bp overhangs utilised to connect DNA fragments in a pre-defined order after restriction release^{217,218}.

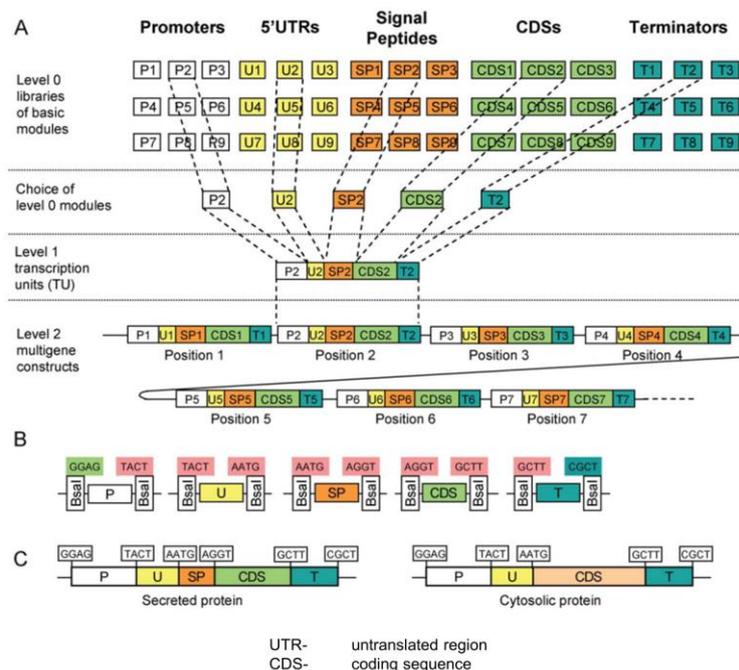

Figure 12: Schematic overview of hierarchical Golden Gate cloning adapted from Weber *et al.*²¹⁸

The flanking 4 base pair sticky overhangs of a basic module can be programmed to guide assembly in a sequential manner (Figure 12), efficiently linking genetic units including promoters, coding sequences, terminators following a pre-defined sequence logic termed as “modular cloning”²¹⁸. Based on the complementarity of the respective parts, transcription units (Level 1) as well as complex multigene complexes can be rapidly assembled within subsequent Golden Gate reactions (Figure 12 B and C).

In recent years, multiple popular plasmid systems for target gene expression in a variety of host organism have been developed, which are all based on the modularity and flexibility enabled by Golden Gate cloning. Examples include systems for *Escherichia coli*²¹⁹, *Bacillus subtilis*²²⁰, various plants^{221–224}, cyanobacteria²²⁵, human cell lines²²⁶, protozoan parasites²²⁶ and amoeba²²⁷. In regard to yeast organisms, plasmid systems for *Saccharomyces cerevisiae*²²⁸, *Schizosaccharomyces pombe*²²⁹, *Yarrowia lipolytica*²³⁰ and *Pichia pastoris*^{207,210} have been developed.

2. Aim of the thesis

Despite being a rather novel enzyme class, firstly reported in 2004³⁰, fungal unspecific peroxygenases (UPOs) have already attracted tremendous interest within the field of biocatalysis. Recent publications state UPOs to be “en route becoming dream catalysts”¹⁰⁰, “swiss army knife for oxyfunctionalisation”⁵² and “the jewel in the crown of C–H oxyfunctionalisation biocatalysts”⁶⁸. Despite their great potential and promise, the widespread use of UPOs within the field of biocatalysis is however still greatly hampered, which can primarily be explained by their challenging heterologous production as naturally being secreted, disulfide-linked and extensively glycosylated enzymes^{52,100,148}. One landmark towards heterologous production of UPOs has been the development of the yeast secretion variant PaDa-I, originating from *AaeUPO*¹⁴⁹, which has enabled a multitude of subsequent application oriented chemistry approaches^{54,102,123,131,135}. PaDa-I is easily accessible by fermentation yielding up to 217 mg/L by utilising the methylotrophic yeast *Pichia pastoris* as well-established production host¹⁵⁰. However, the construction of PaDa-I required an extensive directed evolution campaign to boost secretion in yeast¹⁴⁹ and so far no wild type UPO could be produced within a heterologous host which is amendable to subsequent high-throughput screening and protein engineering.

The major aim of this thesis is therefore the expansion of the currently available panel of fungal peroxygenases which can be produced using a heterologous host. Inspired by the previous success regarding the evolution of *AaeUPO* towards secretion in yeast¹⁴⁹, we focused our efforts on developing modular secretion systems in the two yeast organisms *Saccharomyces cerevisiae* and *Pichia pastoris*. As signal peptide optimisation proved to be a vital factor¹⁴⁹, we intended to build flexible molecular circuits, which allow for the modular construction of versatile UPO expression units in a simple and efficient manner.

In **Chapter I** we aim for the development of a new mutagenesis platform based on the highly efficient Golden Gate cloning technology. By employing the modular, programmable characteristics of Golden Gate cloning, we want to build a mutagenesis platform enabling targeted as well randomised single and multiple-site saturation mutagenesis further aided by automated primer design. We believe that this system can be of great interest for the entire community of biocatalysis.

Building upon the modular Golden Gate logic previously established, within **Chapter II** we aim to expand the system towards modular secretion systems in the yeast organisms *Saccharomyces cerevisiae* and *Pichia pastoris*. As test set, we choose four wild type UPOs to be firstly heterologously produced in yeast. To demonstrate the high appeal of implementing UPOs into chemical synthesis workflows we further aim to exploit stereoselective hydroxylation reactions on a preparative scale.

By combining the developed methods and achieved results of **Chapter I** and **Chapter II** we aim to conduct several directed evolution campaigns to tailor UPOs towards novel substrate

conversions. **Chapter III** targets the construction of chimeric long-type peroxygenases, consisting out of three genetic templates and identification of resulting hydroxylation capability by employing a novel versatile GC-MS high-throughput approach. Within **Chapter IV** we intend to evolve a novel wild type UPO towards the chemo- and regioselective aromatic hydroxylation of naphthalene and derivatives as well as stereoselective benzylic hydroxylation of indane and 1,2,3,4-tetrahydronaphthalene. By further expanding the versatile GC-MS high-throughput setup in **Chapter V** we plan to challenge variant libraries derived from a novel wild type UPO towards the conversion of various non-activated alkane and alkene substrates.

In the concluding **Chapter VI**, we aim to further expand and optimise the previously introduced modular yeast secretion workflow within the industrial highly relevant yeast *Pichia pastoris*. By implementation of an additional promoter shuffling module, consisting of eleven strong methanol-inducible promoters, we plan to improve the yields of previously tested UPOs as well as to firstly produce several novel UPOs.

3. Chapter I

this chapter has been published as:

Golden Mutagenesis: An efficient multi-site-saturation mutagenesis approach by Golden Gate cloning with automated primer design

by: **Pascal Püllmann**^{*}, Chris Ulpinnis^{*}, Sylvestre Marillonnet, Ramona Gruetzner, Steffen Neumann & Martin J. Weissenborn

This chapter summarises the development of a versatile mutagenesis platform allowing for the introduction of defined as well as randomised amino acid substitutions based on the principles of modular Golden Gate cloning. Therefore, we have developed a novel Golden Gate logic for mutagenesis, a compatible *E. coli* expression plasmid allowing for colour-based Agar plate selection and most notably a freeware online tool for the rapid and reliable design of the corresponding mutagenesis primer. As a showcase application study of the system, we could simultaneously randomise up to five residues within a target gene sequence with outstanding efficiency, thereby creating a sequence space of 248832 distinct protein variants.

Golden Mutagenesis: An efficient multi-site-saturation mutagenesis approach by Golden Gate cloning with automated primer design

Pascal Püllmann¹, Chris Ulpinnis¹, Sylvestre Marillonnet¹, Ramona Gruetzner¹, Steffen Neumann^{1,3} & Martin J. Weissenborn^{1,2}

Site-directed methods for the generation of genetic diversity are essential tools in the field of directed enzyme evolution. The Golden Gate cloning technique has been proven to be an efficient tool for a variety of cloning setups. The utilization of restriction enzymes which cut outside of their recognition domain allows the assembly of multiple gene fragments obtained by PCR amplification without altering the open reading frame of the reconstituted gene. We have developed a protocol, termed Golden Mutagenesis that allows the rapid, straightforward, reliable and inexpensive construction of mutagenesis libraries. One to five amino acid positions within a coding sequence could be altered simultaneously using a protocol which can be performed within one day. To facilitate the implementation of this technique, a software library and web application for automated primer design and for the graphical evaluation of the randomization success based on the sequencing results was developed. This allows facile primer design and application of Golden Mutagenesis also for laboratories, which are not specialized in molecular biology.

Directed evolution endeavors require highly efficient molecular cloning techniques to simultaneously alter multiple residues in a rapid, reproducible and cost-effective manner. It is moreover desirable to avoid nucleobase distribution bias in the created library and ideally produce statistical distributions depending on the chosen degeneracy. In recent years, targeted combinatorial approaches for directed evolution such as CASTing^{1,2} or iterative saturation mutagenesis (ISM)^{3,4} have evolved as successful and widely applied techniques for protein engineering using “smart” directed evolution. A general requirement for these approaches is the ability to efficiently alter specific protein residues in a simultaneous manner.

Commonly employed techniques for single site-saturation mutagenesis include, amongst others, MOD-PCR (Mutagenic Oligonucleotide-Directed PCR Amplification)⁵, Codon Cassette Mutagenesis⁶, Overlap Extension PCR⁷, Megaprimer PCR⁸ and the commercial kit QuikChange[®]⁹. However, the successful generation of high-quality libraries of gene sequences containing multiple randomization sites often requires more sophisticated methods to achieve a high success rate. Recent developments to address this issue include the introduction of Omnicchange¹⁰, Darwin Assembly¹¹, and ISOR¹².

To facilitate the design of primers utilizing various mutagenesis techniques, computer tools were developed amongst others for Gibson Assembly (<https://nebuilder.neb.com/#/>), gene domestication and assembly for Golden Gate cloning¹³ and primer design for cloning and site-saturation mutagenesis using GeneGenie¹⁴. The use of gene synthesis as a mutagenic tool in directed evolution approaches was carefully assessed by Reetz and co-workers¹⁵. By using high-fidelity on-chip gene synthesis and cloning by overlap extension PCR followed by classical type II restriction digest and gene ligation into the expression vector, they were able to obtain an excellent 97% ratio of the overall possible gene diversity. They concluded that the application of gene synthesis is likely to become a powerful alternative to established PCR-based randomization protocols, if the overall costs of this type

(email: martin.weissenborn@ipb-halle.de)

of library creation continue to drop. Also, the combination of high fidelity DNA synthesis of mutagenized DNA fragments with efficient and seamless cloning techniques such as Golden Gate cloning or Gibson Assembly could represent an interesting next developmental step.

Golden Gate cloning was introduced in 2008¹⁶ and is based on the use of type IIS restriction enzymes. This subclass of restriction enzymes is defined by their ability to cleave double-stranded DNA templates outside of their recognition site. A remarkable feature of the technique is that it allows to perform restriction and ligation reactions in a time and cost saving one-pot reaction setup with an overall efficiency of correct assembly close to 100%^{17–23}. Since the type IIS recognition sequence is liberated from the insert upon successful restriction, a correctly integrated insert cannot be digested further—this feature enables an efficient one-pot restriction ligation setup leading to steadily increasing number of recombinant constructs in the course of the setup. In the case of classical type II enzymes, which digest double-stranded DNA within their recognition site, the site is restored upon ligation into the expression plasmid and therefore creating a competition scenario between restriction and ligation, if performed in a one-pot scenario and leading to overall low efficiencies of recombination. An increasingly large number of Golden Gate compatible plasmids is furthermore accessible through the non-profit plasmid repository Addgene.

Arguably the most valuable feature of the Golden Gate cloning technique is that it allows highly specific assembly of several gene fragments, which is mediated through the generation of four base pair overhangs that flank the fragments after restriction. 240 unique overhangs (4⁴–16 palindromic sequences) can be employed to join adjacent fragments, therefore enabling broad applicability in the field of multiple site-directed mutagenesis. Correct assembly occurs in a seamless manner, *i.e.* frameshift mutations are avoided and the original open reading frame of the target gene is restored. Furthermore, the conducted blue/orange against white bacterial colony color screening enables the distinction of negative events (no restriction/ligation) and hence save screening effort, since it allows the exclusion of those events for subsequent testing. In contrast to other widespread mutagenesis techniques like QuikChange[®], amplification of the acceptor plasmid backbone via PCR is not necessary for Golden Gate cloning. This circumstance eliminates the risk of introducing unwanted mutations within the plasmid backbone. However, so far only very few examples were reported employing Golden Gate cloning for mutagenesis in the context of directed evolution approaches^{16,24,25}.

We have developed and optimized a hands-on protocol for the implementation of Golden Gate-based Mutagenesis (coined Golden Mutagenesis) in any laboratory focusing on rational or random protein engineering. The entire Golden Mutagenesis protocol requires solely three enzymes (BsaI, BbsI and a DNA ligase) and one to two different plasmids (one cloning and one *E. coli* expression plasmid)—a Golden Gate compatible pET28b based expression vector was constructed and deposited at Addgene. The success of the respective Golden Gate digestion-ligation approach can be directly observed and estimated on the agar plate due to the utilized blue (LacZ; pAGM9121) or orange (CRed; pAGM22082_CRed) selection markers. Furthermore, an open source web tool was developed to facilitate primer design and analysis of the created randomized library, which is accessible at <https://msbi.ipb-halle.de/GoldenMutagenesisWeb/>. This tool allows the user to upload any gene sequence of interest, select a number of protein residues that shall be mutagenized and select a suitable cloning/expression vector depending on the desired cloning task. All required primers for Golden Gate cloning are automatically designed after specifying the desired codon degeneracies (*e.g.* NDT, NNK) and differences in melting temperatures of the corresponding primer pairs are minimized and set to a default T_m value of 60 °C. Following physical construction of the randomization library and sequencing of a pooled library, consisting of >n distinct bacterial colonies (depending on the number of randomization sites and the chosen degeneracy), the generated randomizations are assessed (.ab1 file format) and illustrated as nucleobase distributions in pie charts. Herein, we present a straightforward technique for multiple-site saturation mutagenesis aided by a web tool for primer design and sequencing analysis.

General concept of Golden Mutagenesis

Extensive information about the conceptual basis of Golden Gate cloning can be found in detail elsewhere^{17,18,26}. Briefly, type IIS restriction enzymes (mostly BsaI or BbsI) are utilized, which cut double-stranded DNA molecules outside of their recognition site. This characteristic feature allows the assembly of DNA fragments in a seamless manner.

Golden Mutagenesis utilizes this above-mentioned cloning and assembly strategy enabling efficient parallel one-pot restriction-ligation procedures. PCR fragments are generated, which carry the terminal type IIS recognition sites and introduce additional specific randomization sites outside of the binding primer sequence. The general structure of the designed oligonucleotides follows this scheme: type IIS recognition site, specified four bp overhang, randomization site and template binding sequence (5' to 3' direction). The generated PCR products are then reassembled in a target expression vector and the resulting genetic library is directly transformed into an *E. coli* expression strain (Fig. 1, left). Direct Golden Gate assembly of multiple PCR fragments, which exhibit several parallel randomization sites may become less efficient with increasing gene fragment numbers and complexity levels. This is due to limitations in ligation efficiency and the generally lower transformation competency of *E. coli* expression strains, if compared to classical cloning strains. Therefore as second strategy was developed were individual gene fragments are subcloned into a cloning vector (pAGM9121) and transformed into an *E. coli* cloning strain. In order to preserve the introduced degeneracy the plasmid DNA preparations of the resulting single gene fragment constructs, are therefore prepared as libraries by direct inoculation of the transformation mixture into a liquid culture. The subcloned gene fragment libraries are then assembled into the final expression vector in the course of a second Golden Gate reaction—no additional PCR step is required (Fig. 1, right). This two-step procedure also opens interesting possibilities in directed evolution approaches like iterative saturation mutagenesis (ISM) by fragmenting the gene into subunits^{1–4}. A gene fragment 1 could be subjected to targeted mutagenesis and subcloned in the cloning vector and finally assembled with the unmodified wildtype gene fragments 2 and 3

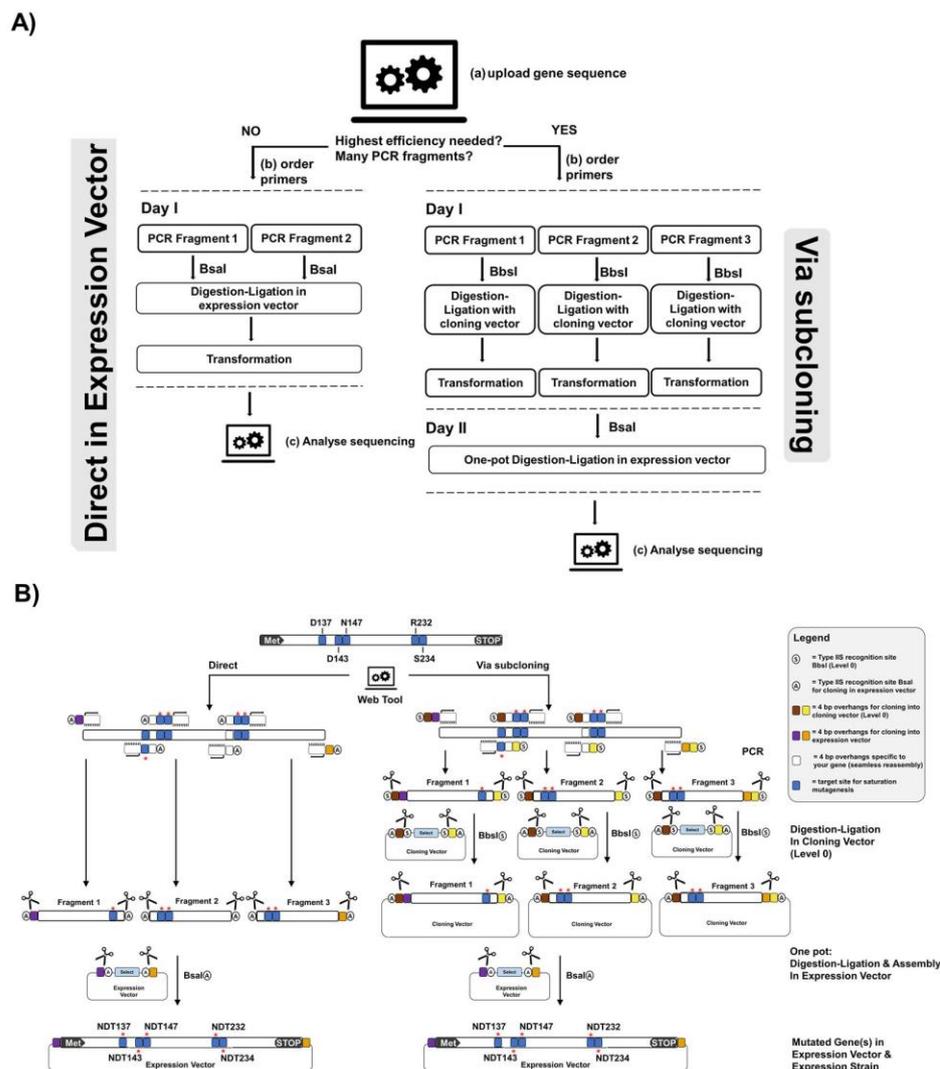

Figure 1. Setup for Golden Mutagenesis. **(A)** Schematic overview of the workflow. After uploading a gene of interest into the web tool, the user can decide whether to perform mutagenesis as a one-step or two-step procedure depending on the number of gene fragments and mutations to be introduced. For the one-step procedure, the program designs primers flanked by BsaI or BbsI sites for direct cloning into the expression or cloning vector. For the two-steps procedure, primers are flanked by BbsI sites and the products are first cloned into an intermediate cloning vector before the final gene reassembly in the expression vector. **(B)** Schematic representation of the two-step procedure. Primers are designed carrying type IIS recognition sites (circle with S = BbsI and circle with A = BsaI) and 4 bp sequences for compatibility with the cloning vector (level 0, brown [5'] and yellow [3']). Additionally, the primers at the 5' and 3' end include specific expression vector (level 2) overhangs (purple and bordeaux-red) and the "inner" primers carry gene-specific 4 bp overhangs for seamless reassembly of the fragments (white). Flanking the template binding part of the primer, randomization sites (blue with a red asterisk) are introduced. In the subsequent one-pot Golden Gate digestion-ligation reaction, BbsI binds to its recognition sequence and creates specific, pre-designed 4 bp overhangs (brown and beige) flanking the mutated PCR fragments, which are complementary to the exposed overhangs in the acceptor vector (cloning vector).

in the expression vector in a second Golden Gate reaction. In a subsequent round, fragment 2 can be subjected to mutagenesis and combined with the before optimized gene fragment 1 and fragment 3. Within this two-step Golden Gate subcloning approach different gene regions can be easily assigned and resulting libraries screened consecutively as envisioned in CASTing and ISM approaches. This offers an efficient approach for a controlled, hierarchical mutagenesis approach that was employed in previous studies in a similar method²⁴.

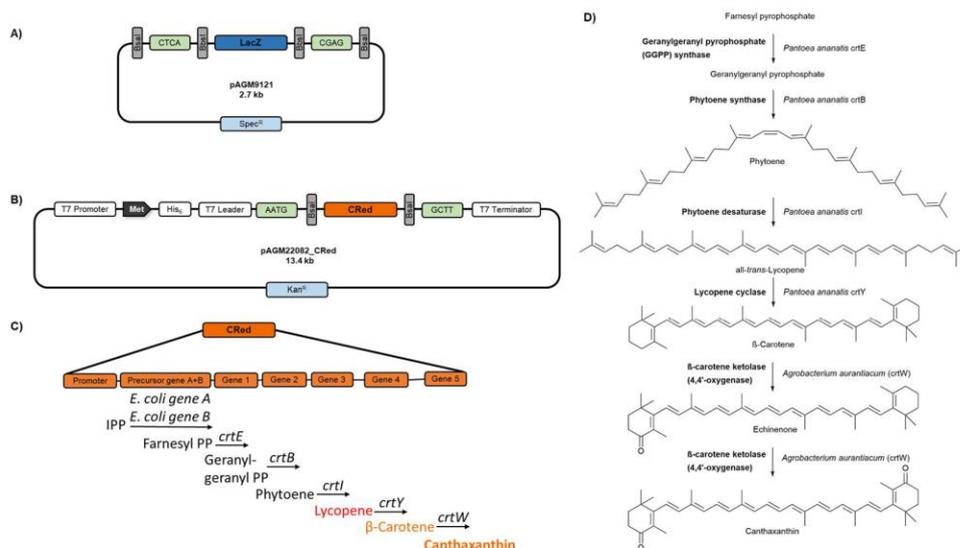

Figure 2. Overview of Golden Gate plasmids used in this study. **(A)** Schematic overview of the universal cloning plasmid (level 0) pAGM9121 which was used for all level 0 cloning approaches in this study. pAGM9121 harbors a LacZ selection marker which is flanked by internal BbsI sites specifying the 4 bp overhangs CTCA (5') and CGAG (3'). Upon correct assembly of the insert, the BbsI sites are eliminated. The insert can be released in a subsequent restriction step based on the flanking BsaI sites (principle of cloning into pAGM22082_CRed plasmid). **(B)** pAGM22082_CRed plasmid constructed in this study is a backbone derivative of the commercial pET28b plasmid harboring a canthaxanthin biosynthesis selection marker²⁸ flanked by internal BsaI sites specifying the 4 bp overhangs AATG (start codon) and GCTT (post stop codon). Cloning of open reading frames into this plasmid is performed utilizing BsaI as restriction enzyme and occurs in frame with a 34 amino acid N-terminal linker, consisting of a hexahistidine- detection and purification tag as well as a T7 leader tag. Target gene expression is regulated by a T7 promoter. **(C)** Overview of CRed selection marker. Consisting of a five-gene synthesis operon, reconstituting an artificial canthaxanthin biosynthesis pathway originating from farnesyl pyrophosphate as substrate and ultimately leading to the intracellular accumulation of the orange carotenoid canthaxanthin. Besides the synthesis unit, also two *E. coli* genes (*E. coli* gene A: isopentenyl-diphosphate delta-isomerase and *E. coli* gene B: 1-deoxy-D-xylulose-5-phosphate synthase) are included for precursor synthesis within the operon. **(D)** A detailed schematic description of the enzymatic reactions leading to canthaxanthin.

The final gene assembly step into the compatible *E. coli* expression vector (pAGM22082_CRed)—either directly from the obtained PCR fragments or via intermediate subcloning of individual fragments—is performed using an *E. coli* BL21(DE3) expression strain, enabling the direct assessment of the protein phenotypes of the respective clones. The DE3 genotype is crucial since it includes a T7 RNA polymerase gene thus enabling T7 promoter-dependent target gene expression. A BL21(DE3) strain harboring an additional pLysS plasmid was chosen in our studies. The pLysS plasmid is introduced to suppress basal expression of T7 RNA polymerase by constitutive expression of T7 lysozyme²⁷. This allows for tight control of gene expression and hence can improve the transformation efficiency in the case of potentially toxic proteins. In our studies, some mutagenesis gene targets seemed to have a strongly negative effect on cell growth (on LB agar plates) leading to overall low colony numbers as well as a substantial accumulation of unmodified expression plasmid. By using the pLysS harboring expression strain based on the possible color distinction mutagenesis libraries with high ratios of target colonies (>99% of recombinant plasmid) could be obtained. Subsequent expression of the cloned gene requires induction of the T7 promoter using IPTG or lactose as an inducer. The screening of colonies containing recombinant constructs without inducing expression of the cloned genes requires a visual selection marker other than the widely spread blue/white LacZ color selection cassette, which requires basal *lac* promoter regulated expression. However, an IPTG/lactose induction would contradict the beneficial effect of the pLysS system. A novel pET28b based *E. coli* expression vector was therefore constructed, which carries an orange dye forming biosynthesis operon (termed CRed) under control of a constitutive promoter. The plasmid pAGM22082_CRed exhibits a T7 promoter for target gene expression and has been deposited at Addgene (plasmid #117225). The CRed selection cassette, which is released upon BsaI restriction digest consists of an eight kb canthaxanthin biosynthesis operon (Fig. 2). This operon consists in total of seven genes—four genes from *Pantoea ananatis* (crtE, crtB, crtI and crtY) converting farnesyl pyrophosphate to β -carotene and an additional gene from *Agrobacterium aurantiacum* (crtW) to oxidize β -carotene to canthaxanthin²⁸. Also two *E. coli* derived genes are included to facilitate the synthesis of the isoprenoid precursor molecules. The more prominent orange color of canthaxanthin in comparison to β -carotene enables an easy detection on LB agar. The CRed marker operon within the pAGM22082 plasmid produces the

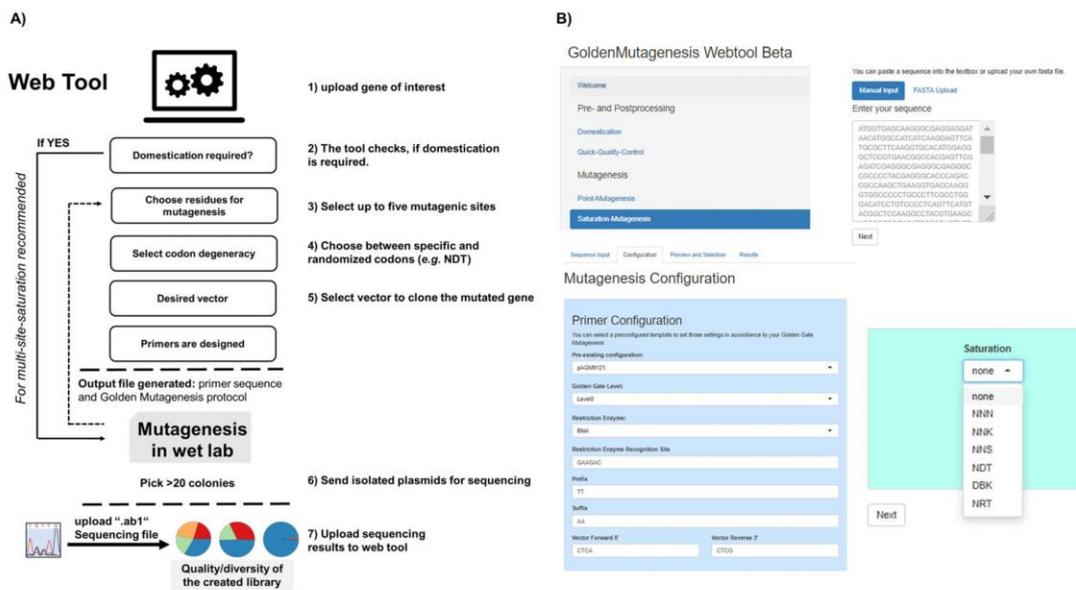

Figure 3. (A) The workflow of the web tool for primer design and quick quality control. (B) Screenshots of the web interface URL: <https://msbi.ipb-halle.de/GoldenMutagenesisWeb/>.

carotenoid independently of an exogenous inducer and therefore allows orange/white selection in basically all common *E. coli* cloning as well as expression strains due to the intracellular accumulation of canthaxanthin (Fig. S5).

Golden Mutagenesis software for *in silico* primer design and quick quality control (QQC)

Since the most challenging part of Golden Mutagenesis is the primer design considering suitable types II recognition sites, specified 4 bp overlaps, minimal melting temperature differences of corresponding primer pairs and specifying the mutation sites, an R package and a web tool was developed in the programming language R. This web application is shown in Fig. 3 and available at <https://msbi.ipb-halle.de/GoldenMutagenesisWeb/>. The source code of the package and an alternative interface based on Jupyter notebooks (deployed with binder²⁹) are available at <https://github.com/ipb-halle/GoldenMutagenesis/>.

The tool is implemented into the overall workflow as shown in Fig. 3A. The user specifies the gene of interest and which residue(s) shall be modified and in which manner (specific vs saturation mutagenesis). Removal of internal type IIS restriction sites (termed domestication) within the gene sequence, which is highly recommended for efficient Golden Gate cloning, can be performed in parallel to the point or saturation mutagenesis step. The requirement for domestication is automatically indicated and suitable silent point mutations for the removal of internal cleavage sites are suggested and implemented by the tool. Primers which are generated by the tool for the purpose of point mutagenesis and domestication additionally take into account the *E. coli* codon usage to avoid the occurrence of rare codons upon mutagenesis which might hamper subsequent protein production. Besides *E. coli* codon usage also eukaryotic (*S. cerevisiae*) and plant (*A. thaliana*) codon usages are selectable options to streamline subsequent gene expression in those organisms using suitable Golden Gate plasmids. For multi-site-saturation mutagenesis, however, it is recommended to perform this domestication step in the “wet lab” before generating the library to provide a clean domesticated gene template prior to mutagenesis. This step will help to maximize the efficiency of the saturation mutagenesis experiment, as fewer PCR products are needed to be amplified and assembled at the same time. This domestication has only to be done once as the starting point of the entire mutagenesis endeavor.

Two different cloning options are available: (a) Direct cloning of PCR fragments into the level 2 expression vector pAGM22082_CRed or level 0 cloning vector pAGM9121 (Fig. 1A, left) or (b) subcloning of individual gene fragments into the cloning vector pAGM9121 followed by an assembly of the subcloned fragments into the expression vector pAGM22082_CRed (Fig. 1A, right). For the mutagenesis of a few residues, leading to 3 or fewer PCR fragments option a) is recommended since it is quicker and can be performed within one day.

The tool calculates and displays the full set of required primers, which carry the distinct type IIS restriction sites, mutagenic sites as well as suitable, matching four bp overhangs for specific sequential gene reassembly. First, the number of fragments is determined based on the distance of the selected mutation sites and a minimal fragment length. The tool decides whether a fragment should cover more than one mutation site, based on the user-specified parameters in the “Mutagenesis Configuration”. For option (a) primers are flanked by BsaI (expression) or BbsI (cloning) sites, while for option (b) primers are generally flanked by BbsI sites to enable cloning into

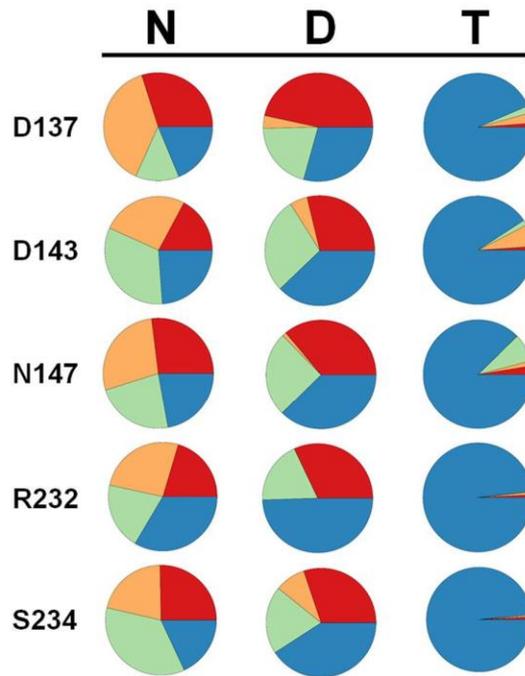

Figure 4. The created randomization libraries can be analyzed using the software tool. Base distribution with the example of a simultaneous NDT codon saturation at 5 residue positions (simultaneous NDT (N = A, T, C, G; D = A, T, G, T = T) randomization of 5 amino acid residues of the enzyme YfeX). Color code: blue: thymine; orange: cytosine; green: guanine and red: adenine.

pAGM9121. In the case of saturation mutagenesis approaches, the designed primers conceptually differ from the design of primers for targeted point mutagenesis, since randomization sites are not suitable for targeted reassembly and hence cannot be positioned within overhang regions, whereas in the case of point mutagenesis the altered genetic information is if possible placed within the four bp overhang to facilitate correct gene fragment rejoining based on the altered information. Randomization sites (Fig. 1B, blue with an asterisk) are introduced between the primer-template binding sequence (3' direction) and the respective four base pair reassembly overhangs (5' direction). Matching primer pairs are automatically calculated and optimized to exhibit minimal differences in melting temperature with a default T_m value of 60 °C^{30,31}. A comprehensive text protocol enabling the user to easily perform all practical steps of the mutagenesis procedure is supplemented by the tool.

To access the quality of the generated library an analysis feature has been constructed and is available to easily assess the efficiency of the performed mutagenesis, a method that has previously been referred to as Quick Quality Control (QQC)³². The sequencing results in a “.ab1” file format containing chromatogram information can be uploaded to the web tool, which is based on sangerseq R package³³. The nucleobase distribution within the randomization sites can then be visualized as pie-charts (Fig. 4).

Developed protocols

Case I: Single site-directed mutagenesis and introduction of the target gene into the Golden Gate System.

As a proof-of-concept for the functionality of the software, the widely used fluorescent protein mCherry³⁴ was used as gene target, with the aim of introducing a single amino acid change (L69V) using a one nucleotide point mutation. The mCherry gene sequence contains an internal BbsI site which is recommended to be removed for Golden Gate cloning since the generally high efficiency of the digestion-ligation reaction is compromised in the case of the internal cleavage site, thus a second nucleotide exchange was envisioned. Therefore, the mCherry gene was split into three gene fragments using PCR. This workflow required a total amount of six primers flanked by BbsI recognition sites (Table S1). All primers were designed with the aid of the web tool, and the prior requirement to remove the internal BbsI restriction site was automatically detected by the program within the point mutagenesis workflow. New genetic information was automatically introduced at the terminal gene regions to provide a suitable type IIS recognition site as well as four bp overhang compatibility with the acceptor plasmid pAGM9121 (Fig. S2). The performed cloning setup led to 29000 bacterial colonies with a 99:1 ratio of white to blue colonies (see Fig. S3 for colony PCR). As mentioned above, it is recommended to perform an initial domestication step (only once required in the entire mutagenesis procedure) prior to the randomization of specific sites to obtain maximal efficiency of the Golden Gate cloning. Alternatively, a subcloning step of individual PCR fragments into a cloning vector and subsequent reassembly of the domesticated, mutated gene

Experiment	1 site via level 2	1 site via level 0	5 residues via level 2	5 residues via level 0
Efficiency ^a	96%	100%	100%	100%
Total amount white to blue/orange colonies	860/0	5000/12	1400/55	1600/29
Ratio white to orange colonies	100	99.8:0.2	96:4	98:2

Table 1. Overview of cloning results for NDT saturation mutagenesis approaches. ^aPercentage of bacterial colonies containing plasmids of the expected size as determined by colony PCR (24 colonies tested in each approach).

in a second step in the expression vector can be performed (Fig. 1). However, if no randomization library but a specific, defined point mutation is required as above, this can preferably be done in one step.

Case II: Multi-Site-Saturation Mutagenesis. Saturation mutagenesis was performed using the sequence of the *E. coli* derived YfeX^{35,36} gene as a template to introduce NDT codon degeneracy at either one or five positions simultaneously. The two strategies presented in Fig. 1B were tested: direct cloning and assembly of the mutagenic PCR fragments into the final expression vector or subcloning each fragment into an intermediate cloning vector, followed by subsequent gene reassembly in the final expression vector.

Direct cloning into the expression vector introducing one NDT saturation site (two PCR fragments) and transformation of the ligation mixture in *E. coli* BL21(DE3) pLysS led to 860 white, recombinant colonies and no orange colony, and a 96% efficiency rate for correct YfeX reassembly—based on quick testing by colony PCR. In the case of the simultaneous saturation mutagenesis of five residues (three PCR fragments) 1400 white and 55 orange colonies were obtained (Table 1). The assembly efficiency was 100% based on 24 quick-tested colonies.

As a consequence of using the subcloning step of the PCR fragments followed by gene reassembly into the expression vector, substantially higher colony numbers were obtained in case of saturation mutagenesis at one position; 5000 white and twelve orange colonies could be obtained (ratio: 99.8:0.2). The efficiency for YfeX gene reassembly proved to be 100% again. In the case of the saturation mutagenesis at 5 sites (three respective fragments), a higher colony number (1600 in total) and a white to orange colony ratio of 98:2 could be achieved, with a ratio of correct white colonies of 100% as determined by analogous quick testing of 24 colonies (Fig. S4).

In this single- as well as multi-site saturation mutagenesis approach of the YfeX gene nearly perfect efficiencies of correct Golden Gate gene reassembly could be achieved. Overall efficiency and fidelity of correct Golden Gate assembly in general, however, might be substantially depending on the nature of the created 4 bp overhang. Previous extensive studies on the fidelity of 4 bp overhangs revealed that certain sequences are joined less efficiently by T4 Ligase, potentially limiting assembly reaction yield, and many can be ligated efficiently to overhangs other than their Watson-Crick complement, thereby leading to overall low fidelity of the Golden Gate assembly reaction^{23,37}.

To access the base distribution within the randomization sites for this five saturation sites (D137, D143, N147, R232 and S234) approach, a QQC was performed and the sequencing results of a pooled library analyzed using the software tool (Fig. 4). The expected NDT distribution pattern could be demonstrated at all 5 targeted positions, with a slight overrepresentation of thymine, which may be caused either by bias within the ordered primer mixtures or also possible due to altered template binding behavior within the primers containing a higher GC content due to more pronounced secondary structure occurrence, leading to less efficient annealing to the gene template. To prove that the overall genetic diversity of the library is not compromised by the diversity of the intermediate subcloning step, libraries obtained at the intermediate fragment subcloning step (level 0) were plated as well, leading to colony numbers of up to 58000 colonies and white to blue ratios of up to 99.7:0.3 (Table S2), thereby easily covering the required genetic diversity within the randomization sites.

Conclusions

A Golden Gate cloning based protocol for the efficient execution of defined site-specific mutations within a gene of interest as well as for the generation of targeted randomization libraries was introduced. Efficient cloning protocols were established—including a novel Golden Gate compatible expression plasmid enabling T7 dependent expression in *E. coli*. The process of primer design was significantly simplified by the development of a freely available open source web tool that moreover facilitates the analysis of the randomization library quality by displaying nucleobase distributions within the envisioned randomization sites. The Golden Mutagenesis technique is in particular suited for streamlining iterative multiple site-saturation techniques like CASTing, ISM and SCSM/DCSM/TCSM protocols.

Methods

General PCR Protocol. Reactions were carried out using standardized conditions. In a final reaction volume of 50 µl 100 ng of plasmid DNA (pET28a_mCherry or pCA24N_YfeX) were added as an amplification template. The pCA24N_YfeX plasmid was derived from the ASKA library³⁸. Final reaction mixtures consisted of 3% (v/v) DMSO; 1x concentrated Phusion Green HF buffer (ThermoFisherScientific, Waltham, US); 0.5 units of Phusion High-Fidelity DNA polymerase (ThermoFisherScientific, Waltham, US); 200 µmol dNTP-Mix (ThermoFisherScientific, Waltham, US) and 200 nmol forward primer and reverse primer (stock solutions dissolved in ddH₂O). PCR reactions were carried out by default under the following conditions: a) initial denaturation: 98 °C (60 s); b) cycling (35 passes in total): 95 °C (15 s), 60 °C (30 s) and 72 °C (90 s per kb amplification product) c) final elongation: 72 °C (10 min). Following PCR the samples were analyzed by agarose gel

electrophoresis (7 V/cm; 45 min) (1 to 2.5% (w/v) agarose (AppliChem, Darmstadt, DE) in TAE buffer), using a 1 kb DNA ladder (ThermoFisherScientific, Waltham, US) as standard for size determination. Therefore a volume of 5 μ l out of the total PCR mixture was loaded onto the agarose gel for analysis. Double-stranded PCR products were visualized under UV light using a Genoplex Imager (VWR, Darmstadt, DE). After confirmation of occurrence and correct band sizes corresponding PCR products (45 μ l) were further purified. PCR products were recovered and purified using a NucleoSpin[®] Gel and PCR Clean-up Kit (Macherey-Nagel, Düren, DE). Concentrations of purified PCR products were determined by absorbance measurements at a wavelength of 260 nm using an infinite F200 pro device (TECAN, Grödig, AT).

Golden Gate cloning procedure. All Golden Gate reactions were performed in a total volume of 15 μ l. The final reaction volume contained 1-fold concentrated T4 ligase buffer (Promega, Madison, US). Prepared reaction mixtures (ligase buffer, acceptor plasmid, insert(s)) was adjusted to 13.5 μ l with ddH₂O. In a final step, the corresponding enzymes were quickly added. First, a volume of 0.5 μ l of the respective restriction enzyme BbsI (5 units; ThermoFisherScientific, Waltham, US) or BsaI-HF[®]v2 (10 units; New England Biolabs, Ipswich, US) and then 1 μ l (1–3 units) of T4 ligase (Promega, Madison, US) was added. Golden Gate reactions were carried out by default under following conditions: a) Enzymatic restriction 37 °C (2 min) [40 passes]; b) Ligation 20 °C (5 min) [40 passes] and c) enzyme inactivation: 80 °C (20 min).

Procedure A: General Transformation. Following the Golden Gate reaction, the whole reaction volume of 15 μ l was used to transform RbCl chemo-competent *E. coli* DH10B cells (aliquot of 50 μ l; 7.1×10^7 cfu/ μ g pUC19 DNA; ThermoFisherScientific, Waltham, US) by heat shock procedure (90 s at 42 °C). After heat shock, cells were recovered in 500 μ l LB medium for 1 h at 37 °C. Transformed cells were plated on LB agar plates (50 μ g ml⁻¹ X-Gal, 100 μ g ml⁻¹ spectinomycin, 150 μ M IPTG). LB agar plates were then incubated overnight at 37 °C. Based on the presence of a LacZ cassette within the cloning site of pAGM9121 a color distinction (blue/white screening) between the unmodified pAGM9121 (blue colonies) and recombinant plasmid (white colonies) is possible. Colony numbers are given with two significant figures³⁹. For colony numbers >50 the agar plates were divided into sections and the counted colonies multiplied with the number of sections.

Procedure B: Subcloning into cloning vector pAGM9121. General transformation procedure as described in procedure A. After recovery, the transformation volume of approx. 550 μ l was split into two fractions. A volume of 50 μ l was used for plating on LB-agar plates (+X-Gal, +spectinomycin, +IPTG) and incubated overnight (37 °C) to evaluate the success of cloning on the following day (desired scenario: low percentage of blue colonies, high percentage and number of white colonies). The remaining volume was used to directly inoculate an overnight liquid culture of 4 ml TB medium (100 μ g ml⁻¹ spectinomycin) to preserve the prior created genetic diversity within the randomization sites of the saturation mutagenesis approach.

Procedure C: Transformation of expression vector pAGM22082_CRed. General transformation procedure as described procedure A, but using RbCl chemo-competent BL21(DE3) pLysS (aliquot of 100 μ l; 2.4×10^7 cfu μ g⁻¹ pUC19 DNA, Merck Millipore, Darmstadt, DE). Transformed cells were plated (50 μ l final volume) on LB agar plates (50 μ g ml⁻¹ kanamycin, 50 μ g ml⁻¹ chloramphenicol). LB agar plates were then incubated overnight at 37 °C. Based on the presence of an artificial bacterial operon responsible for canthaxanthin biosynthesis (termed CRed) within the cloning site of pAGM22082_CRed a color distinction between the unmodified pAGM22082_CRed (orange colonies; intracellular accumulation of canthaxanthin) and recombinant plasmid (white colonies; loss of operon) is possible.

Golden Gate cloning (cloning vector): point mutagenesis. General reaction conditions as described in section 2 using BbsI as restriction enzyme. The three PCR fragments for Golden Gate reassembly into the cloning vector (level 0) were prepared as described in section 1. The universal level 0 plasmid pAGM9121, which carries a LacZ selection marker, was used as acceptor plasmid for reassembly of mCherry in a final concentration of 20 fmol. Plasmid pAGM9121 can be obtained through Addgene (plasmid #51833). The three PCR fragments were added in equimolar amounts (20 fmol each). The transformation was performed according to procedure A.

Golden Gate cloning into cloning vector pAGM9121: individual fragment cloning for saturation mutagenesis. General reaction conditions as described in section 2 using BbsI as restriction enzyme. Individual PCR fragments for Golden Gate assembly into the cloning vector were prepared as described in section 1. The plasmid pAGM9121 was used as acceptor plasmid in a final concentration of 20 fmol. PCR fragments were added in equimolar amounts relative to the plasmid (20 fmol each) and subsequent Golden Gate reactions were performed in parallel (e.g. two fragments in two parallel cloning approaches). The transformation was performed according to procedure B.

Direct Golden Gate cloning of PCR fragments into expression vector pAGM22082. General reaction conditions as described in section 2 using BsaI-HF[®]v2 as restriction enzyme. The PCR fragments for Golden Gate reassembly into level 2 were prepared as described in section 1. The level 2 expression plasmid pAGM22082_CRed was used as acceptor plasmid for reassembly of YfeX in a final concentration of 20 fmol. Plasmid pAGM22082_CRed can be obtained through Addgene (plasmid #117225). Respective PCR fragments were added in equimolar amount compared to the plasmid (20 fmol each). The transformation was performed according to procedure C.

Golden Gate cloning into expression vector pAGM22082 from cloning vector. General reaction conditions as described in section 2 using BsaI-HF^{v2} as restriction enzyme. Starting from overnight grown liquid cultures of respective pAGM9121 constructs (prepared as described in section 5) plasmid mixtures were prepared using a NucleoSpin Plasmid Kit (Macherey-Nagel, Düren, DE). Following the preparation, the concentrations of purified plasmid DNA were determined by absorbance measurements at a wavelength of 260 nm using an infinite F200 pro device (TECAN, Grödig, AUT). The level 2 expression plasmid pAGM22082_CRed was used as acceptor plasmid for reassembly of YfeX in a final concentration of 20 fmol. Respective pAGM9121 donor plasmids were added in equimolar amounts relative to pAGM22082_CRed plasmid (20 fmol each). The transformation was performed according to procedure C.

Efficiency control of gene reassembly via colony PCR. After performing the Golden Gate cloning reactions the success rate of correct gene reassembly was determined by the means of colony PCR. PCR reactions were carried out using standardized conditions in a total reaction volume of 25 µl. Final reaction mixtures consisted of: 1x concentrated GoTaq[®] Green buffer (Promega, Madison, US); 0.7 units of GoTaq[®] DNA Polymerase (Promega, Madison, US); 150 µmol dNTP-Mix (ThermoFisherScientific, Waltham, US) and 150 nmol forward primer and reverse primer (stock solutions dissolved in ddH₂O). As corresponding primer pairs, two options were chosen: a) forward and reverse primer of the corresponding acceptor plasmid or b) forward amplification primer of the insert and reverse primer of the acceptor plasmid. As amplification template, a clearly separated single *E. coli* colony was scratched off the LB agar plate using a sterile toothpick and transferred to the respective PCR tube.

PCR reactions were carried out by default using the following conditions: a) initial denaturation: 98 °C (120 s); b) cycling [35 passes]: 95 °C (15 s), 55 °C (30 s) and 72 °C (60 s per kb amplification product) c) final elongation: 72 °C (6 min). Following PCR the samples were analyzed by agarose gel electrophoresis (7 V/cm; 45 min) (1% (w/v) agarose (AppliChem, Darmstadt, DE) in TAE buffer), using a 1 kb DNA Ladder (ThermoFisherScientific, Waltham, US) as the standard for size determination. Double-stranded PCR products were visualized under UV light using a Genoplex Imager (VWR, Darmstadt, DE).

Quick quality control (QQC) of randomization through sequencing. To assess the created genetic diversity in the prior mutagenesis step(s), a sequencing step was implemented³². At least 150 white colonies were pooled and inoculated into 4 ml TB medium (50 µg ml⁻¹ kanamycin, 50 µg ml⁻¹ chloramphenicol). The liquid culture was incubated overnight (37 °C) for subsequent plasmid preparation. The plasmid mixtures were prepared as described in section 7. After determining the concentration, the elution volume was split into two tubes (approx. 18 µl each), the respective forward (pAGM22082_for) or reverse primer (pAGM22082_rev) at a concentration of 1 µM added and samples sent to Eurofins Genomics (Ebersberg, DE) for sequencing. Sequencing results were received in a.ab1 file format the following day.

Data Availability

Vectors and inserts: The universal level 0 Golden Gate cloning vector pAGM9121 (plasmid #51833) and the newly designed pET-based level 2 *E. coli* expression vector pAGM22082_CRed (#117225) can be obtained through the non-profit plasmid depository Addgene (www.addgene.org). Detailed information on the usage of the R Package can be found in the R vignettes and documentation files provided as supplemental material. They cover three examples (point mutagenesis, site-saturation mutagenesis and graphical illustration of quick quality control (QQC)) including the created data. The web application is available at <https://msbi.ipb-halle.de/GoldenMutagenesisWeb/>. The source code and an alternative interface based on Jupyter notebooks are available at <https://github.com/ipb-halle/GoldenMutagenesis/> under the LGPL-3.0 Open Source license.

This chapter represents the core findings of this dissertation, namely the design and construction of modular Golden Gate systems for the efficient secretion of novel fungal peroxygenases utilising the yeast organisms *Saccharomyces cerevisiae* and *Pichia pastoris* as heterologous hosts. Applying the modular signal peptide shuffling concept, the secretion of a previously engineered UPO could be increased and furthermore four wild type peroxygenases produced for the first time in yeast— two of those enzymes derived from secretome data and prior not being annotated as UPOs. The achieved shake flask titres of up to 24 mg UPO per litre represent the highest reported titres for the recombinant production of UPOs within this setup to date. The chapter was concluded by the successful implementation of the newly discovered UPOs for the preparative scale stereoselective hydroxylation of a pharmaceutically relevant core building block within an initial proof-of-concept approach.

OPEN

A modular two yeast species secretion system for the production and preparative application of unspecific peroxygenases

Pascal Püllmann¹, Anja Knorrscheidt¹, Judith Münch¹, Paul R. Palme¹, Wolfgang Hoehenwarter¹, Sylvestre Marillonnet¹, Miguel Alcalde², Bernhard Westermann^{1,3} & Martin J. Weissenborn^{1,3}✉

Fungal unspecific peroxygenases (UPOs) represent an enzyme class catalysing versatile oxyfunctionalisation reactions on a broad substrate scope. They are occurring as secreted, glycosylated proteins bearing a haem-thiolate active site and rely on hydrogen peroxide as the oxygen source. However, their heterologous production in a fast-growing organism suitable for high throughput screening has only succeeded once—enabled by an intensive directed evolution campaign. We developed and applied a modular Golden Gate-based secretion system, allowing the first production of four active UPOs in yeast, their one-step purification and application in an enantioselective conversion on a preparative scale. The Golden Gate setup was designed to be universally applicable and consists of the three module types: i) signal peptides for secretion, ii) UPO genes, and iii) protein tags for purification and split-GFP detection. The modular episomal system is suitable for use in *Saccharomyces cerevisiae* and was transferred to episomal and chromosomally integrated expression cassettes in *Pichia pastoris*. Shake flask productions in *Pichia pastoris* yielded up to 24 mg/L secreted UPO enzyme, which was employed for the preparative scale conversion of a phenethylamine derivative reaching 98.6 % ee. Our results demonstrate a rapid, modular yeast secretion workflow of UPOs yielding preparative scale enantioselective biotransformations.

Fungal unspecific peroxygenases (UPOs) have recently emerged as novel versatile hydroxylation biocatalysts. They solely rely on hydrogen peroxide as cosubstrate reaching impressive total turnover numbers for sp³-carbon hydroxylation of up to 300000^{1–4}. Further UPO catalysed reactions include aromatic hydroxylation, heteroatom oxidation, halogenation and carbon–carbon double bond epoxidation⁵. Due to their high oxyfunctionalisation versatility and activity, while solely requiring hydrogen peroxide and being independent of auxiliary electron transport proteins and expensive cofactors, UPOs have attracted keen interest in the biocatalysis field^{5–7}. Current challenges include suboptimal regio- and enantioselectivities towards specific substrates and the extremely limited panel of available UPOs, impeding broader screening setups to find a suitable catalyst to perform a particular reaction. There is an estimated number of more than 4000 putative UPO genes currently annotated and widely spread within the fungal kingdom representing just a small fraction of the available genetic diversity⁸.

To provide further insight into the natural function of UPOs as well as broadening the available substrate scope, it is crucial to access more enzymes from diverse phylogenetic backgrounds. Recent studies reported on the conversion of testosterone by a UPO derived from an ascomycetous mould, a reaction that could not be performed by any other UPO thus far⁹. This new activity further emphasises the limitations of the small available UPO panel. It would be further highly desirable to heterologously produce UPOs utilising fast-growing standard laboratory hosts such as bacteria or yeast. These organisms would facilitate protein engineering and allow directed evolution campaigns for tailoring UPOs towards desirable traits such as increased stability, regio- and enantioselectivity.

Although substantial work has been invested into the heterologous expression of the firstly discovered *Agrocybe aegerita* UPO (*AaeUPO*) using the yeast *Saccharomyces cerevisiae*, sufficient protein amounts of 8 mg/L were obtained as the result of an intensive directed evolution campaign¹⁰. This fundamental work led to several successful UPO application studies on the conversion of a range of substrates from agrochemicals to pharmaceuticals^{11–14}. The yeast secretion variant PaDa-I (hereinafter: *AaeUPO**) was adapted subsequently for large-scale protein production by utilising the methylotrophic yeast *Pichia pastoris* (syn. *Komagataella phaffii*) reaching recombinant protein titres of 217 mg/L within a bioreactor setup¹⁵.

The successful production was achieved by the introduction of nine amino acid exchanges. Four of these were localised within the 43 amino acid signal peptide (SP), which orchestrates protein secretion in the natural fungal host as well as in *S. cerevisiae*. The engineered signal peptide combined with the wild-type *AaeUPO* enzyme resulted in a 27-fold increase in protein secretion yield highlighting the paramount importance of the respective signal peptide for heterologous production as already shown by others^{16–21}. Recent studies report the production of UPOs in *E. coli*^{22,23}. However, it remains elusive whether these recombinant peroxygenases harbour comparable activities and stabilities if compared to UPOs produced in eukaryotic hosts. The reported expression yields are substantially lower compared to *S. cerevisiae* raising the question, whether enough functional protein could be produced for laboratory evolution campaigns.

Golden Gate cloning has proven to be an invaluable synthetic biology tool enabling seamless assembly of gene fragments utilising type II restriction enzymes^{24–32}. By using type II restriction enzymes, defined 4 base pair sticky overhangs can be created for reassembly. These overhangs can be easily specified by PCR, allowing a sequence defined, efficient and seamless assembly of nine and more gene fragments in a one-pot and one-step digestion-ligation manner^{25,32,33}.

For the detection of the target protein secretion in small volumetric amounts of yeast supernatant, a sensitive, high-throughput suitable, and protein-specific assay would be highly beneficial. Previously reported split-GFP (green fluorescent protein) systems, which rely on tagging the protein of interest with a short amino acid peptide tag and subsequent GFP reconstitution, present an ideal tool for this task^{34,35}.

In this study, we envisioned a tripartite Golden Gate-based modular system. This system consists of the modules 'signal peptide', 'UPO gene' and 'protein-tag' (Fig. 1A). The 'protein-tag' module combines affinity-based purification as well as the enzyme quantification by split-GFP. This *S. cerevisiae* expression system gave rise to a rapid workflow starting from UPO genes to heterologously produced and purified UPOs within 2 to 4 weeks (Supplementary Fig. 2).

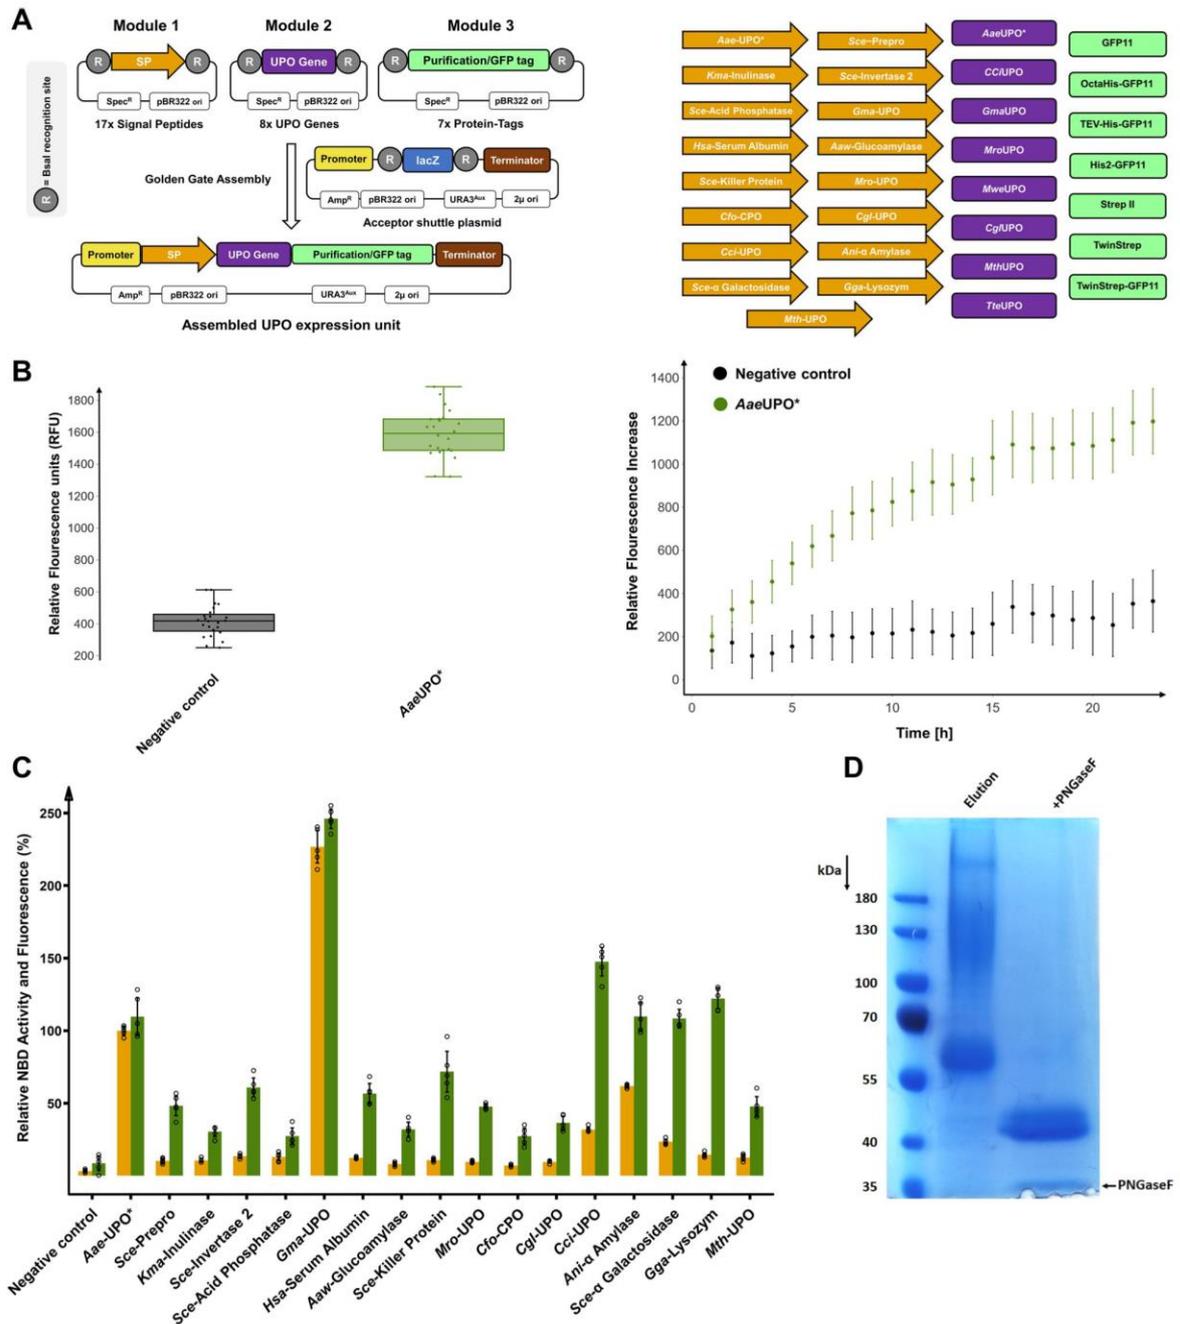

To unlock access to higher protein amounts, we designed two fully compatible episomal and one integrative plasmid for UPO production in the methylotrophic yeast *Pichia pastoris*. In total, four active UPOs were heterologously produced in yeast for the first time. The high recombinant UPO yields using *P. pastoris* enabled the enantioselective hydroxylation of a phenethylamine derivative on a preparative scale.

Results

The modular Golden Gate UPO expression system. Three modules were designed for pre-defined assembly into an episomal *S. cerevisiae* shuttle expression plasmid. We created 32 modules (Fig. 1A) consisting of 17 signal peptides (Module 1), 8 UPO genes (Module 2) and 7 protein-tags (Module 3) derived from a broad phylogenetic background as summarised in Table 1. Module 3 is employed for affinity-based enzyme purification and/or split-GFP-based protein quantification. To verify the envisioned system for protein quantification, the C-terminal GFP11 detection tag (Module 3) was assembled with the previously evolved UPO signal peptide *Aae-UPO** (Module 1) and the engineered peroxygenase *AaeUPO** (Module 2)^{10,36}. Target gene expression is controlled by a GAL 1.3 promoter, which is repressed in the presence of glucose and strongly induced by galactose, being a truncated version of the widely used GAL1 promoter. The successful split-GFP assay was validated by a significant fluorescence response in the sample with the secreted protein (Fig. 1B).

Module 1, exhibiting 17 distinct signal peptides (SP), is the pivotal part for guiding protein secretion. The diverse signal peptide library consists of sequences originating from *S. cerevisiae*, further yeast organisms, basidiomycetes, ascomycetes and animals (Supplementary Table 4). Seven signal peptide sequences originate from (putative) UPOs and a closely related chloroperoxidase (*CfuCPO*). To demonstrate the importance of the signal peptide, we assembled the *AaeUPO** gene (Module 2) and the GFP11 tag (Module 3) with each of the 17 signal peptides (Module 1). UPO secretion levels were monitored by enzymatic activity using the 5-nitro-1,3-benzodioxole (NBD)³⁷ assay as well as split-GFP detection (Fig. 1C).

All constructs showed significant secretion levels and enzymatic activities. The signal peptides *Cci-UPO*, *Ani-α Amylase*, *Sce-α Galactosidase* and *Gga-Lysozyme* led to similar protein concentrations as the evolved signal peptide *Aae-UPO**. The signal peptide *Gma-UPO* resulted in a more than doubled activity and secretion of the *AaeUPO** enzyme relative to the evolved *Aae-UPO** signal peptide (220% increase). This observation is particularly impressive considering that the signal peptide *Aae-UPO** was evolved for the optimised secretion of *AaeUPO** in *S. cerevisiae* by subjecting it to several rounds of directed evolution¹⁰. The signal peptide *Gma-UPO* originates from the

putative *Galerina marginata* UPO (*GmaUPO*). When correlating normalised enzymatic activity and split-GFP-based fluorescence values of the signal peptide library, in most cases, higher fluorescence levels than activity values were measured. This observation indicates the occurrence of differing *AaeUPO*⁺ enzyme variants depending on respective signal peptide cleavage. This could be due to the great diversity of the utilised signal peptides likely resulting in differing *N*-termini and affecting the enzymatic activity of the processed enzyme.

To give rise to a general, one-step protein purification protocol for UPOs, Module 3 was further extended to allow for simultaneous affinity-based protein purification and GFP11-

based fluorescence detection. Several versions of the GFP11 tag in combination with Strep[®] or Hexa/Octahistidine-affinity tags were generated and tested (Supplementary Table 5)^{38,39}. We used the protein tags with the previously identified beneficial combination of signal peptide (*Gma*-UPO, Module 1) and UPO (*AaeUPO*⁺, Module 2) and identified the TwinStrep-GFP11 protein tag as most suitable. This tag consists of a double 8 amino acid Strep II tag (Twin-Strep-tag)⁴⁰ and a C-terminal GFP11 sequence. Comparison of the modules GFP11 and TwinStrep-GFP11 revealed unaltered enzymatic activities but a significantly higher fluorescence response for the TwinStrep-GFP11 construct (Supplementary Fig. 3). This difference is

Fig. 1 The Golden Gate system consisting of the modules signal peptide, UPO gene and protein-tag and its functional verification regarding split-GFP assay, signal peptide shuffling and purification using the model UPO *AaeUPO in *S. cerevisiae*.** **A** *Left*: Concept of the modular Golden Gate system as a tripartite system, consisting of signal peptide (SP; contains ATG start codon), UPO gene (lacking start and stop codon) and C-terminal Tag (contains stop codon). *Right*: Overview of the individual parts of the modular shuffling systems, containing 17 signal peptides, 8 UPO genes and 7 C-terminal protein tags. Detailed sequence information of all parts can be found in Supplementary Tables 4 and 5. **B** Quantification of the UPO secretion in *S. cerevisiae* using the split-GFP system. Two constructs were utilised for testing, namely a previously derived yeast secretion variant of *AaeUPO* (*AaeUPO**) and further including a C-terminal GFP11. The acceptor shuttle plasmid (pAGT572_Nemo 2.0) was used as negative control. *Left*: biological replicates ($n = 24$) of *AaeUPO** and the negative control were screened within the split-GFP assay. Relative fluorescence units (RFU) were measured at 0 and 72 h after adding GFP1-10. Values are shown as boxplots (*AaeUPO**: median = 1589, s.d. 8.9%; negative control: median = 416, s.d. 22.6%) with individual data points shown as dots. *Right*: Continuous fluorescence measurements (24 h; 23 time points) of each construct. Data are mean of fluorescence – background (background = first measurement after 1 h) \pm s.d. of biological replicates ($n = 24$). **C** Screening of the constructed signal peptide shuffling library utilising *AaeUPO** as reference protein. Values for 5-nitro-1,3-benzodioxole (NBD) conversion (orange bars) and fluorescence by split-GFP assay (green bars) were normalised to the previously used *AaeUPO* SP* -*AaeUPO** construct (100%). Data are mean \pm s.d. of biological replicates ($n = 5$). Primary data are displayed within the Source data file. Detailed information on the origin and the sequence of the signal peptides can be found in Supplementary Table 4. **D** SDS-PAGE analysis of *AaeUPO** after one step TwinStrep tag[®] purification, utilising the designed TwinStrep-GFP11 purification/detection combination tag. Additionally, *AaeUPO** was subjected to enzymatic deglycosylation by PNGaseF and analysed (right lane).

probably due to better accessibility of the terminal GFP11 portion since the overall size of the tag is increased (27 vs. 59 amino acids), and several flexible linkers are included. SDS PAGE analysis revealed the successful one-step purification of the mature protein *AaeUPO** (Fig. 1D). The positioning of an N-terminal Strep II protein-tag revealed greatly diminished UPO activity (Supplementary Fig. 4) and was therefore not further investigated.

Utilisation of the modular system for the heterologous production of novel UPOs. To demonstrate that the modular system can provide quick access to produced UPOs, we choose seven UPO genes to be expressed in *S. cerevisiae* while three being undescribed putative UPOs. Four UPOs were previously described and produced in their natural hosts—*Marasmius rotula* UPO (*MroUPO*)⁴¹, *Marasmius wettsteinii* UPO (*MweUPO*)⁸, *Chaetomium globosum* UPO (*CglUPO*)⁹—or heterologously expressed in an *Aspergillus oryzae* strain (*Coprinopsis cinerea* UPO (*CciUPO*))⁴².

Two putative UPO sequences were selected based on sequence alignments and data bank searches using the short-type peroxygenase *CglUPO* as a template. Two sequences were retrieved, originating from fungi classified as thermophilic: *Myceliophthora thermophila* (*MthUPO*) and *Thielavia terrestris* (*TteUPO*)⁴³, bearing 72% and 51% sequence identity to *CglUPO*, respectively (Supplementary Table 10). The predicted long-type UPO gene *GmaUPO* is derived from the basidiomycete *Galerina marginata* and was selected based on its high sequence identity (71 %) with *AaeUPO**.

All genes were introduced as modules (Module 2) into the Golden Gate system and subjected to random shuffling utilising all 17 signal peptides (Module 1).

Out of the seven UPO genes, six could be secreted by *S. cerevisiae* in combination with at least two signal peptides (Fig. 2A). *CciUPO* exhibited no secretion with any of the signal peptides. *MweUPO* and *GmaUPO* were identified through the split-GFP assay, but no activity was detected using the colorimetric 2,6-dimethoxyphenol (DMP) assay¹². *MweUPO*, *MroUPO* and *CglUPO* were the only UPOs, which showed the highest activities with their endogenous signal peptides, *MroUPO* and *MweUPO* sharing the identical native signal peptide. *MthUPO* and *TteUPO* showed remarkable secretion levels within the microtiter plate setup, leading to 17-fold (*MthUPO*) and 50-fold (*TteUPO*) split-GFP signal intensities above background level. A high signal peptide promiscuity was observed for *MthUPO* and *TteUPO* with at least 5 and 8 suitable signal peptides, respectively (Supplementary Figs. 5 and 6).

Purification and characterisation of the identified UPOs. All successfully secreted UPOs in combination with their best signal peptides were equipped with the TwinStrep-GFP11 tag, produced in 1 L shake flask scale, and purified by affinity chromatography. The occurrence and primary sequence of each UPO was confirmed by tryptic digest and mass spectrometric peptide analysis (Supplementary Tables 6 and 8). *AaeUPO** analysis revealed the amino acids ‘EPGLPP’ being the first detectable residues at the N-terminus in accordance with previous results¹⁵. This finding indicates that the employed signal peptide *Gma-UPO* leads to a comparable cleavage pattern as the evolved *Aae-UPO** signal peptide. The split-GFP response and the NBD activity also exhibited the same ratio for both signal peptides (Fig. 1C), which further strengthens the point of a similar cleavage pattern. *MroUPO* and *MweUPO* were produced utilising their native signal peptide (*Mro-UPO* SP). Fragments derived from the signal peptide *Mro-UPO* (11 amino acids for *MroUPO* and 9 amino acids for *MweUPO*) were identified by MS analysis, suggesting a different cleavage pattern compared to the natural host⁸. Obtained N-termini of *GmaUPO* and *MthUPO* are in good agreement with the predicted cleavage sites based on alignments with the enzymes *AaeUPO** and *CglUPO*, respectively. The N-terminus of *CglUPO* could not be resolved. For *TteUPO*, a peptide fragment of 10 amino acids of the utilised signal peptide (*ScE-Prepro*) was identified.

GmaUPO and *MweUPO* were not further studied as the purified enzymes did not exhibit any activity towards the colorimetric peroxygenase substrates DMP and NBD. For these enzymes, we were not able to obtain pure elution samples for subsequent measurements of native as well as CO differential absorption spectra.

Biochemical parameters were therefore determined for *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO*. UV absorption profiles showed the expected characteristic peroxygenase haem-thiolate features. A Soret band with a maximum around 420 nm (*MroUPO*: 419 nm; *CglUPO*: 418 nm; *MthUPO*: 420 nm and *TteUPO*: 419 nm) and two Q-bands in the range of 537 to 546 and 569 to 573 nm (Fig. 2B)² were detected. *CglUPO* revealed a broader Soret band shape as well as less pronounced Q-bands. The respective carbon monoxide complexes exhibited absorption maxima around 444 nm (Supplementary Fig. 7).

Protein purity and glycosylation were analysed by SDS-PAGE. Native deglycosylation was performed using PNGaseF (Supplementary Fig. 8). All obtained molecular weights after deglycosylation were in approximate agreement with the calculated weight based on the primary sequence and peptide analysis by mass spectrometry. *MroUPO* exhibited a defined band at approx. 42

Table 1 Origin of utilised UPO genes and signal peptides for target protein secretion.

Descriptor	Type	Organism	Descriptor	Type	Organism
AaeUPO*	Secretion engineered UPO	<i>Agrobacterium aegerita</i>	Cfo-CPO	Chloroperoxidase signal peptide	<i>Caldariomyces fumago</i>
GmaUPO	Wild-type UPO	<i>Galerina marginata</i>	Cgi-UPO	UPO signal peptide	<i>Coprinopsis cinerea</i>
CciUPO	Wild-type UPO	<i>Coprinopsis cinerea</i>	Sce- α Galactosidase	α Galactosidase signal peptide	<i>Saccharomyces cerevisiae</i>
MroUPO	Wild-type UPO	<i>Marasmius rotula</i>	Sce-Prepro	α factor signal peptide	<i>Saccharomyces cerevisiae</i>
MweUPO	Wild-type UPO	<i>Marasmius weinsteini</i>	Sce-Invertase 2	Invertase 2 signal peptide	<i>Saccharomyces cerevisiae</i>
CgiUPO	Wild-type UPO	<i>Chaetomium globosum</i>	Gma-UPO	UPO signal peptide	<i>Galerina marginata</i>
MthUPO	Wild-type UPO	<i>Myceliophthora thermophila</i>	Aaw-Glucoamylase	Glucoamylase signal peptide	<i>Aspergillus awamori</i>
TteUPO	Wild-type UPO	<i>Thielavia terrestris</i>	Mro-UPO	UPO signal peptide	<i>Marasmius rotula</i>
Aae-UPO*	Engineered signal peptide of AaeUPO	<i>Agrobacterium aegerita</i>	Cgl-UPO	UPO signal peptide	<i>Chaetomium globosum</i>
Kma-Inulinase	Inulinase signal peptide	<i>Kluyveromyces marxianus</i>	Ari- α Amylase	α Amylase signal peptide	<i>Aspergillus niger</i>
Sce-Acid Phosphatase	Acid phosphatase signal peptide	<i>Saccharomyces cerevisiae</i>	Gga-Lysozym	Lysozyme signal peptide	<i>Gallus gallus</i>
Hsa-Serum Albumin	Serum albumin signal peptide	<i>Homo sapiens</i>	Mth-UPO	UPO signal peptide	<i>Myceliophthora thermophila</i>
Sce-Killer Protein	Killer protein signal peptide	<i>Saccharomyces cerevisiae</i>			

kDa that was slightly shifted towards lower molecular weight after deglycosylation. *CglUPO* revealed a smeared band in the range of 55–130 kDa. Deglycosylation led to the occurrence of two distinct protein bands of approx. 37 and 33 kDa indicating different protein subtypes. *MthUPO* and *TteUPO* showed an intensive smeared band in the range of 55–200 kDa. This smear was converted into distinct protein bands upon deglycosylation with approx. 38 kDa and 36 kDa for *MthUPO* and *TteUPO*, respectively.

To gain insights into the impact of the glycosylation on the activity of the respective enzyme, UPOs were deglycosylated in the native state and assessed for their activity towards NBD (Supplementary Fig. 9). The enzymatic activity of *MroUPO* was in comparison least affected with a decrease of approx. 80%, whereas in the case of *CglUPO* no activity could be obtained after deglycosylation. The activity was substantially impaired as well for *TteUPO* and *MthUPO*, leading to a complete loss and approx. 85% decrease, respectively, in enzymatic activity.

We next evaluated the pH-dependencies of the enzymes using NBD as a substrate (Fig. 2C). *MroUPO*, *MthUPO* and *TteUPO* exhibited a similar profile with maximum activity at slightly acidic conditions (pH 5), whereas *CglUPO*'s activity optimum was detected at pH 7. *TteUPO* showed a broader tolerance towards lower pH values, retaining medium (pH 3; 40%) and high activity (pH 4.0; 80%) at acidic conditions. The obtained values for *MroUPO* and *CglUPO* are in good agreement with previous data obtained with homologously produced enzyme^{9,41}.

Enzymatic epoxidation and hydroxylation experiments. The heterologously produced UPOs were tested towards their substrate specificity and activities by investigating three distinct reaction types: aromatic hydroxylation (sp^2 -carbon), alkene epoxidation and the benzylic hydroxylation (sp^3 -carbon) of phenylalkanes with varying alkyl chain lengths from two to five carbons (Fig. 3). All reactions were performed under the same conditions and assessed for the achieved turnover number (TON) within one hour. Substantially differing behaviour could be observed between *AaeUPO** and the novel heterologously produced UPOs regarding substrate conversion, specific product formation and stereoselectivity. *AaeUPO** proved to be the only enzyme displaying a high specificity for single hydroxylation of naphthalene leading to 1-naphthol (92% of the formed product, Fig. 3A). The other UPOs exhibited a strong tendency for further oxidation leading to the dione product 1,4-naphthoquinone. The epoxidation of styrene (Fig. 3B) was efficiently catalysed by *AaeUPO** (4580 TON) in combination with a poor stereoselectivity (2% *ee*). *CglUPO* exhibited comparable epoxidation activities (4110 TON) and an enantioselectivity of 44% *ee*. For *MthUPO*, TON decreased to 1100 but revealed the highest stereoselectivity (45% *ee*). The studies of the benzylic hydroxylation of phenylalkanes—ranging from phenylethane to phenylpentane—confirmed the known preference of *AaeUPO** towards short alkane chain length (Fig. 3C)³. Starting from 4500 turnovers for the conversion of phenylethane and deteriorating to no product formation and only traces of benzylic hydroxylation using phenylbutane and phenylpentane, respectively (for other product formations see Supplementary Fig. 17). *CglUPO* and *MthUPO* exhibited an inverted trend with increasing product formations for longer alkyl chain lengths, exhibiting the lowest activity for the phenylethane hydroxylation.

The highest activity was detected in both cases using phenylbutane (*CglUPO*: 1670 TON, *MthUPO*: 1490 TON) with only slightly decreased activity for phenylpentane as a substrate and the only significant side-product being the further oxidation of the benzylic alcohol to the corresponding ketone

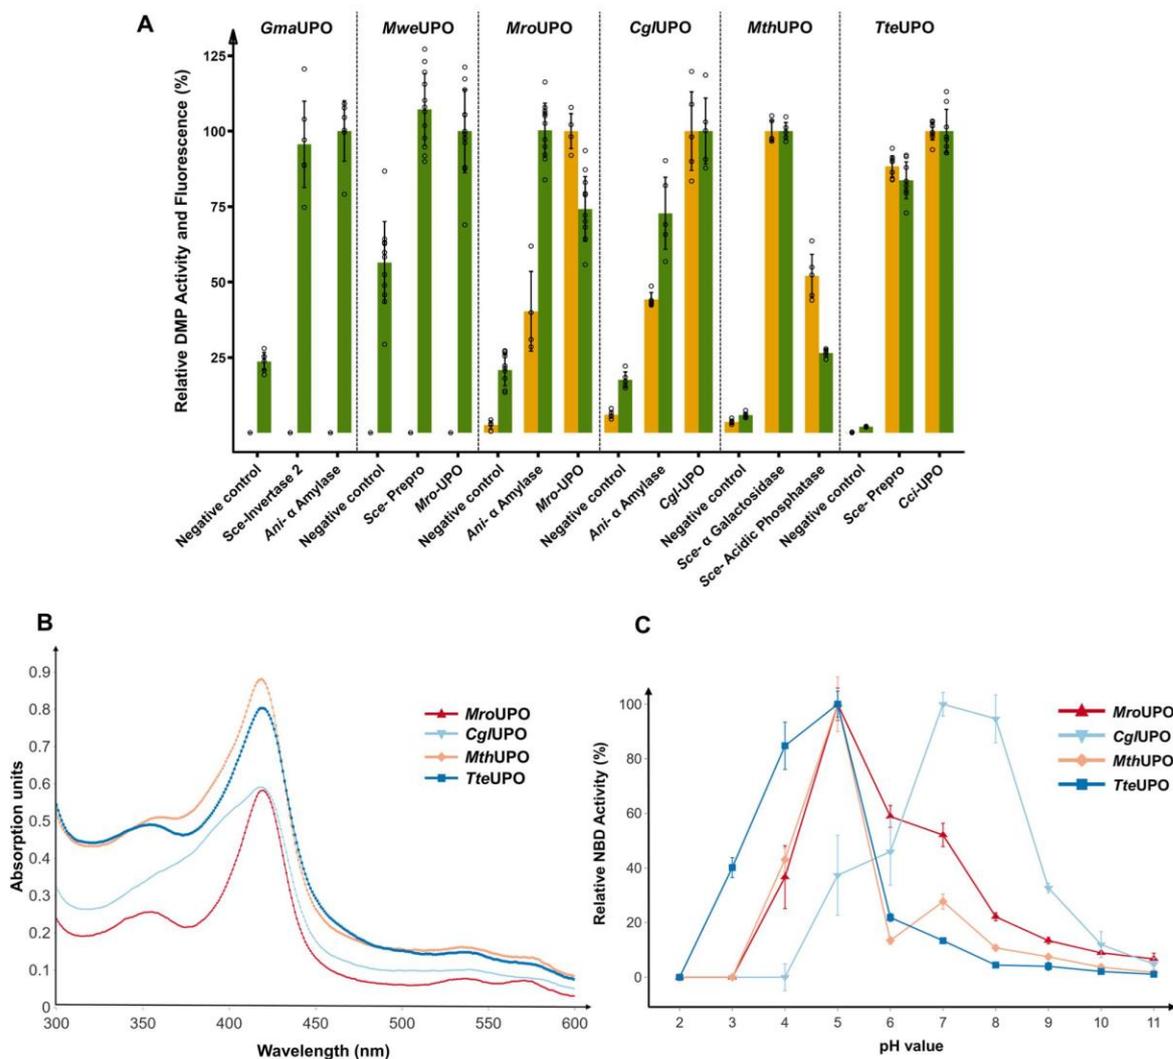

Fig. 2 Through signal peptide shuffling identified novel UPO construct and their analysis of UV absorption spectra and pH profiles. **A** Golden Gate signal peptide shuffling was applied for the testing of described and putative UPO genes, and the two best signal peptide/UPO gene combinations are displayed. *GmaUPO*, *MweUPO*, *MroUPO* and *CglUPO* were screened in combination with a GFP11-tag. *MthUPO* and *TteUPO* were screened using the TwinStrep-GFP11 protein tag. UPO enzyme activity was determined by monitoring the conversion of 2,6-dimethoxyphenol (DMP) to coerulignone. The highest average fluorescence (split-GFP) and conversion values (DMP) within one enzyme panel were set to 100%, and the other values normalised accordingly. Data are mean \pm s.d. of biological replicates ($n \geq 4$). Corresponding primary data are displayed within the Source data file. **B** UV-Vis absorption spectra of the purified peroxygenases *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO* in the wavelength range between 300 and 600 nm (measurement interval: 1 nm). **C** pH profiles of *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO* catalysed enzymatic conversion of 5-nitro-1,3-benzodioxole (NBD) to 4-nitrocatechol. The highest mean activity of a respective enzyme was set to 100% and the other values normalised accordingly. Data are means \pm s.d. of measurements performed in triplicates. Corresponding primary data are displayed within the Source data file.

(Supplementary Fig. 17). *TteUPO* showed a similar preference towards long-chain phenylalkanes with the highest TON for phenylpentane conversion (500 TON). *TteUPO* represented the only UPO with a significant specificity towards the formation of the *S* alcohol enantiomer for phenylpropane and phenylbutane. For phenylpentane, it revealed the formation of the opposite alcohol enantiomer than the other tested UPOs as well.

Expanding the modular UPO secretion system to *Pichia pastoris*. The methylotrophic yeast *P. pastoris* (syn. *Komagataella phaffii*) constitutes an attractive heterologous production host with a steadily growing toolbox of valuable synthetic biology parts

such as plasmids, promoters and signal peptides^{44,45}. *P. pastoris* can reach high cell densities, efficiently perform post-translational modifications such as glycosylation and disulfide-linkage and offers a set of strong and tightly regulated promoters for target gene expression. Amongst other factors, these properties render *P. pastoris* a widely used eukaryotic host for the large-scale industrial production of therapeutic proteins and enzymes⁴⁶. We investigated the adaptation of the modular system for use in *P. pastoris*. Therefore, two novel episomal *P. pastoris* expression plasmids were designed and assembled. They contain a previously described autonomously replicating sequence coined panARS, which confers episomal stability and a hygromycin B marker gene

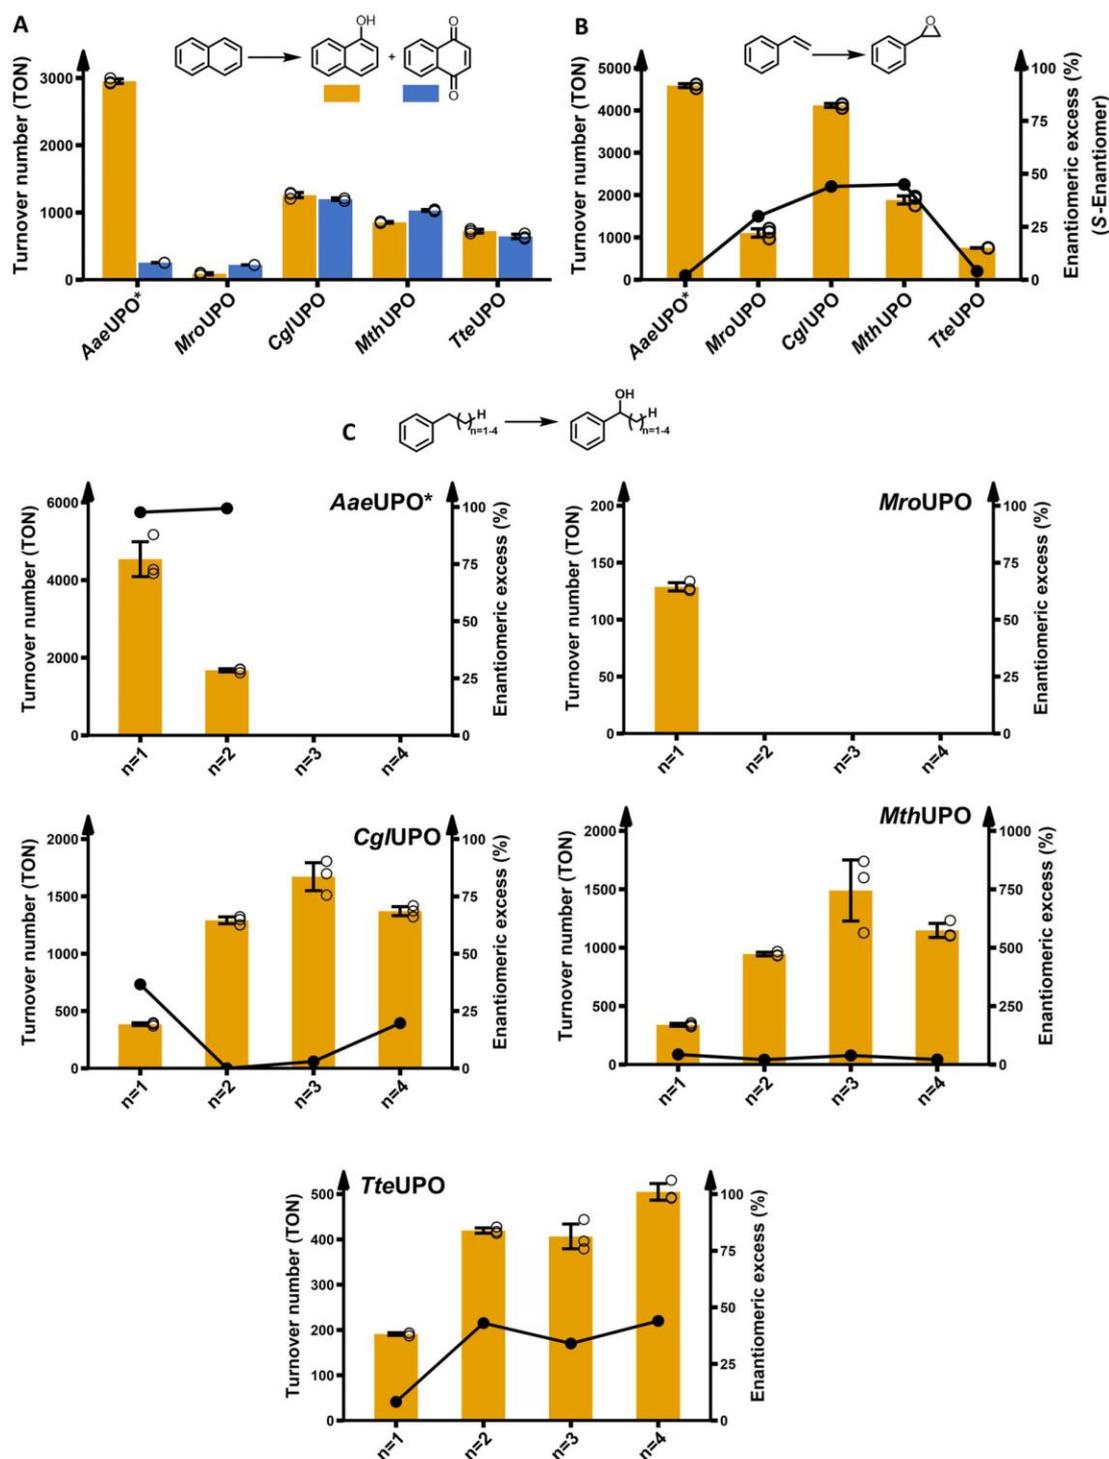

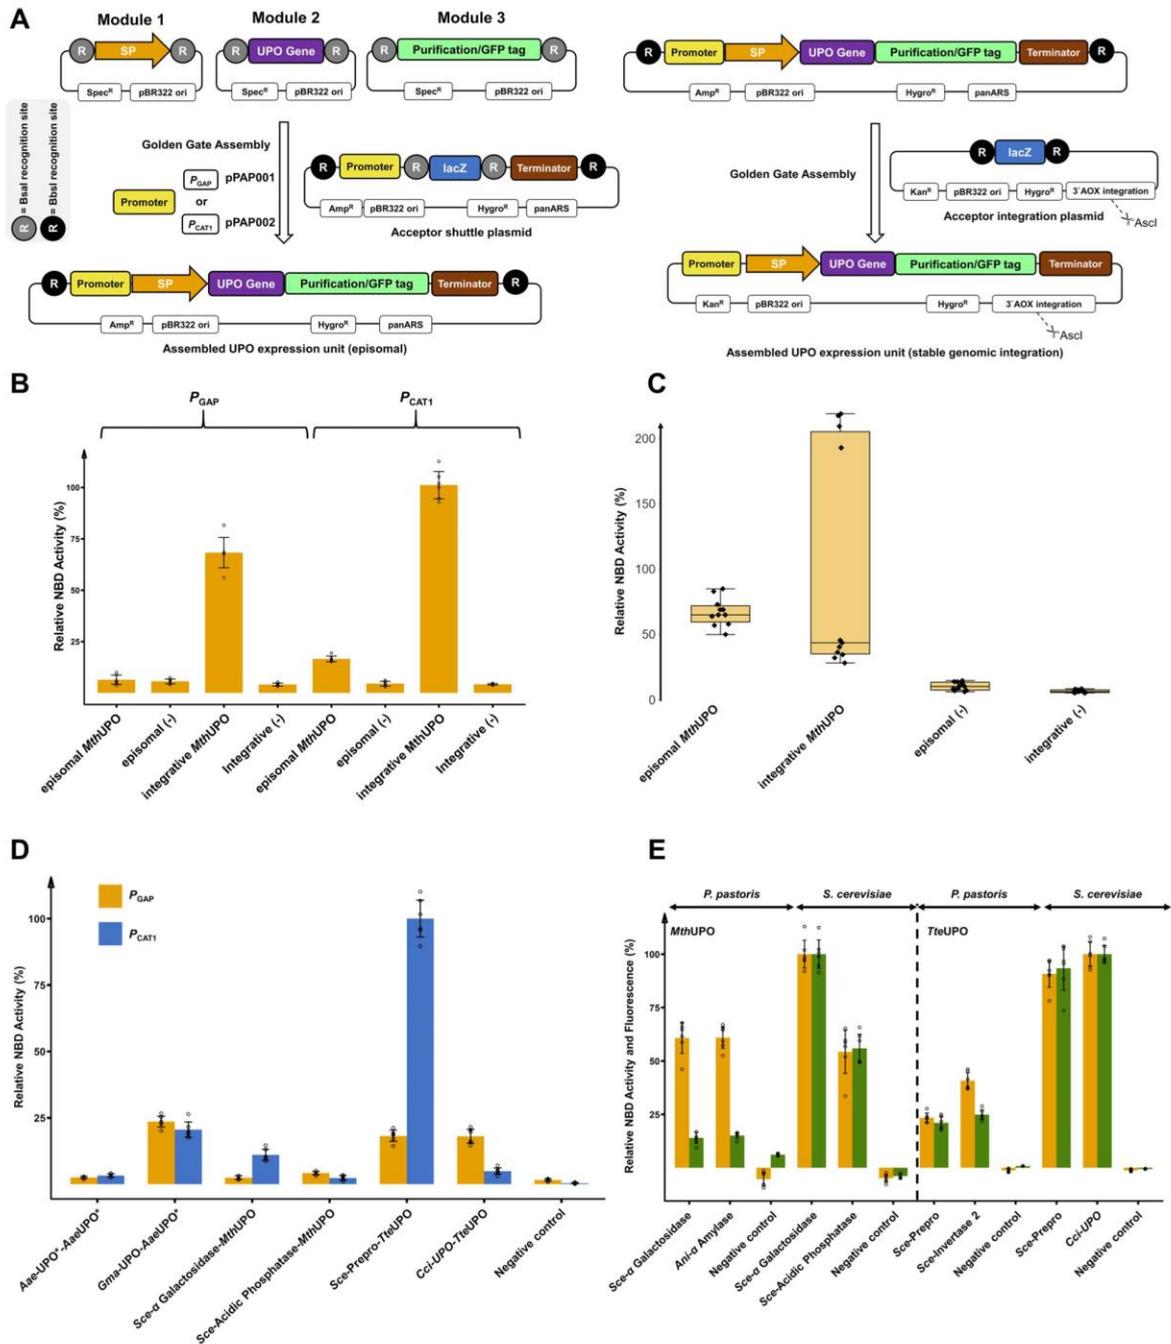

Fig. 3 Enzymatic activity assessment of the peroxygenases regarding aromatic hydroxylation, epoxidation and sp^3 -carbon hydroxylation. All reactions were performed for 1 h using 1 mM of substrate. Bar charts display the obtained turnover numbers (TON) within one hour. The lines correspond to the enantiomeric excess %. Data are mean \pm s.d. measurements derived from biological triplicates with individual data points shown as circles. See supplementary information for further details. **A** Conversion of naphthalene to naphthol and 1,4-naphthoquinone. **B** Conversion of styrene to styrene oxide. **C** A homologous row of phenylethane, phenylpropane, phenylbutane and phenylpentane hydroxylation, respectively, focusing on hydroxylation of the benzylic carbon. The alcohol enantiomer is indicated by an (R) or (S). The exact enantiomer for phenylpentane was not determined. See Supplementary Fig. 17 for occurrence of side-products. For *MroUPO* catalysed conversion of phenylethane no enantioselectivity could be determined.

for antibiotic selection^{47–49}. The constructed episomal plasmids differ by the employed promoter: the strong constitutive glyceraldehyde-3-phosphate dehydrogenase promoter (P_{GAP} , plasmid pPAP001) and the recently described strong methanol inducible catalase 1 promoter (P_{CAT1} , pPAP002)⁵⁰. The plasmids were constructed to allow direct implementation of the tripartite modular UPO secretion system, consisting of Module 1 (signal peptide), Module 2 (UPO gene) and Module 3 (C-terminal tag, Fig. 4A; left). To further allow the genomic integration to generate stable *P. pastoris* cell lines for antibiotic-free large-scale enzyme production in shake flasks or fermenters, a third plasmid

(pPAP003) was constructed. The episomal plasmids are designed to enable direct transfer of the identified best transcription unit (promoter-signal peptide-gene-tag-terminator) combination to the integration plasmid. This transfer requires only an additional Golden Gate assembly reaction using the restriction enzyme BbsI (Fig. 4A; right).

We tested all *P. pastoris* plasmids using the newly discovered peroxygenase *MthUPO* in combination with the *Sce-α* Galactosidase signal peptide. The constructs proved to be functional and led to an NBD conversion signal (Fig. 4B). P_{GAP} -based secretion was generally lower in comparison to P_{CAT1} , and the episomal

Fig. 4 The compatible modular Golden Gate setup utilising episomal and integrative *P. pastoris* plasmids and its application. **A** Left: Overview of the designed episomal *P. pastoris* screening setup. All previously created basic modules are compatible to be used within this system. Two episomal plasmids were designed harbouring the constitutive strong promoter P_{GAP} or the strong inducible promoter P_{CAT1} . Right: Identified gene constructs can be directly transferred in a one-pot Golden Gate reaction (+BbsI) from the episomal plasmid to an integrative plasmid. After linearisation (AsclI digest) this plasmid can be integrated into the genomic 3'AOX region of *P. pastoris*. **B** Comparison of relative activities of 5-nitro-1,3-benzodioxole (NBD) conversion for different *P. pastoris* constructs bearing the tripartite combination of α Galactosidase signal peptide-MthUPO-TwinStrep-GFP11. P_{GAP} bearing constructs were screened utilising Glucose (1.5% (w/v)) as sole carbon source. P_{CAT1} bearing constructs were screened utilising a dual feeding strategy (0.5% (v/v) glycerol and 1.5% (v/v) methanol) as primary and inducible carbon sources. The highest expression mean is set to 100% and all data normalised. Data are mean \pm s.d. of biological replicates ($n = 6$) originating from streak outs of one previously screened colony of the respective construct. **C** Comparison of relative activities of NBD conversion of P_{CAT1} -based constructs bearing the tripartite combination of α Galactosidase signal peptide-MthUPO-TwinStrep-GFP11. Box plots of biological replicates ($n = 11$) of individual *P. pastoris* colonies for each construct. The highest expression mean is set to 100% and all data normalised (episomal MthUPO: median = 65, s.d. 15.0%; integrative MthUPO: median = 44, s.d. 83.3%; episomal (-): median = 10, s.d. 28.2%; integrative (-): median = 6, s.d. 16.4%). **D** Comparison of relative activities of NBD conversion for different episomal *P. pastoris* constructs (6 biological replicates each) using the indicated signal peptide-UPO combinations as well as a TwinStrep-GFP11 tag. P_{GAP} (yellow bars) and P_{CAT1} (blue bars). The highest expression is set to 100%, and all data are normalised accordingly. Data are mean \pm of biological replicates ($n = 6$). **E** Direct comparison of episomal UPO production of the two best signal peptide-UPO combinations for MthUPO and TteUPO as identified by a previously performed signal peptide shuffling approach in both yeast species. Episomal *P. pastoris* expressions utilising P_{CAT1} . The highest mean expression and activity for each enzyme is set to 100%, and all data are normalised. Data are mean \pm s.d. of biological replicates ($n = 6$). NBD conversion activity (orange) and relative fluorescence units (green). All primary data are displayed within the Source data file.

P_{GAP} MthUPO activity was not distinguishable from the negative control. The integrative plasmids outperformed their episomal counterparts significantly with a factor of approx. 5 for P_{CAT1} . A similar observation however in a varying degree was made testing the enzymes AaeUPO* and TteUPO (Supplementary Fig. 10), indicating that the integrative constructs are in general promoting higher UPO secretion levels than their episomal counterparts.

To gain insights into interclonal variabilities of UPO secretion, episomal and integrative plasmids were transformed into *P. pastoris*. Individual colonies were cultivated and tested for UPO secretion. The episomal construct showed diminished mean activity but a substantially lower clonal variability than the integrative plasmid when tested with NBD (Fig. 4C). This high variability of the secretion level for the integrative plasmid is presumably due to divergent numbers of copy insertions into the *P. pastoris* genome, which is a commonly occurring feature in this organism^{51–53}, and might also lead based on the Hygromycin B selection marker to different colony sizes (Supplementary Fig. 11).

To investigate and compare the secretion levels of episomal P_{GAP} and P_{CAT1} harbouring plasmids, twelve constructs were generated harbouring the peroxygenases AaeUPO*, MthUPO and TteUPO. All promoter combinations (P_{GAP} and P_{CAT1}) and the two previously identified signal peptides were constructed in combination with the respective UPO gene and analysed for NBD activity. All constructs resulted in a significant NBD conversion (Fig. 4D). The previously observed 220% improved AaeUPO* secretion in *S. cerevisiae* by combining AaeUPO* with the signal peptide Gma-UPO was found to be even more pronounced using the episomal *P. pastoris* constructs (P_{CAT1} : 620%). Besides the striking influence of the promoter on the secretion level, also the combination of the signal peptide and the promoter proved to be pivotal. For TteUPO, using the promoter P_{CAT1} in combination with the Sce-Prepro signal peptide led to the highest detected activity with a 20-fold higher signal compared to the Cci-UPO signal peptide. The same signal peptide variations employing the P_{GAP} promoter, however, resulted in similar secretion levels. This demonstrates besides the crucial role of the chosen signal peptide (Figs. 1C and 2A) an additionally pivotal synergistic influence of the promoter/signal peptide combination on the UPO secretion.

To gain insights into the different signal peptide preferences for secretion in *P. pastoris*, the signal peptide shuffling approach was repeated in *P. pastoris* using MthUPO and TteUPO and choosing the episomal P_{CAT1} bearing plasmid

(Supplementary Figs. 12 and 13). For MthUPO the signal peptides Sce- α Galactosidase and Ani- α Amylase proved to be most suitable, and Sce-Prepro and Sce-Invertase 2 were identified as top hits for TteUPO. Interestingly, Sce-Invertase 2 has not been identified amongst the top hits in *S. cerevisiae* whereas the best signal peptide (Cci-UPO) for secretion in *S. cerevisiae* (Fig. 4D) was not identified in the *P. pastoris* screen.

To compare episomal *S. cerevisiae* and *P. pastoris* secretion, the two best performing constructs for MthUPO and TteUPO were selected. This species comparison (Fig. 4E) indicates that the episomal *S. cerevisiae* secretion is superior to the episomal *P. pastoris* production. In the case of MthUPO, both *P. pastoris* constructs led to approx. 60% of NBD conversion in comparison to the most suitable *S. cerevisiae* construct, while already exhibiting higher NBD conversion rates than the second most suitable signal peptide for secretion in *S. cerevisiae* (Sce-Acidic Phosphatase). The split-GFP fluorescence assay revealed a diminished response for the *P. pastoris* setup relative to the *S. cerevisiae* constructs. Regarding TteUPO, the best *P. pastoris* construct (Sce-Invertase 2) led to approx. 40% of relative NBD conversion when compared to the best *S. cerevisiae* construct (Cci-UPO). For TteUPO the split GFP assay followed a linear pattern when comparing species, without revealing a diminished response for *P. pastoris*.

Comparison of shake flask UPO production in *P. pastoris* and *S. cerevisiae*.

By using the constructed integrative plasmid pPAP003 and the P_{CAT1} promoter, stable *P. pastoris* cell lines were constructed to produce five UPOs: AaeUPO*, MroUPO, CglUPO, MthUPO and TteUPO (Fig. 5A). Utilising *P. pastoris* as host led to substantially higher production titres in all cases, except for TteUPO. The rather low yields of MroUPO and CglUPO produced in *S. cerevisiae* could be increased substantially when using *P. pastoris* (MroUPO: 3-fold, CglUPO: 15-fold). The MthUPO production yield was improved 5-fold. Regarding TteUPO, the product titre was decreased in *P. pastoris* by approx. 20%, however, still maintaining an overall high yield. The production titres of *S. cerevisiae* derived TteUPO (17 mg/L), and *P. pastoris* derived MthUPO (24 mg/L) are the highest yields for shake flask cultivation of recombinant fungal peroxygenases reported thus far. The transfer of the expression system to a fed-batch bioreactor might further elevate protein titres due to the higher cell densities achievable. In previous work, this transfer into a bioreactor resulted in 27-fold improved product titre of

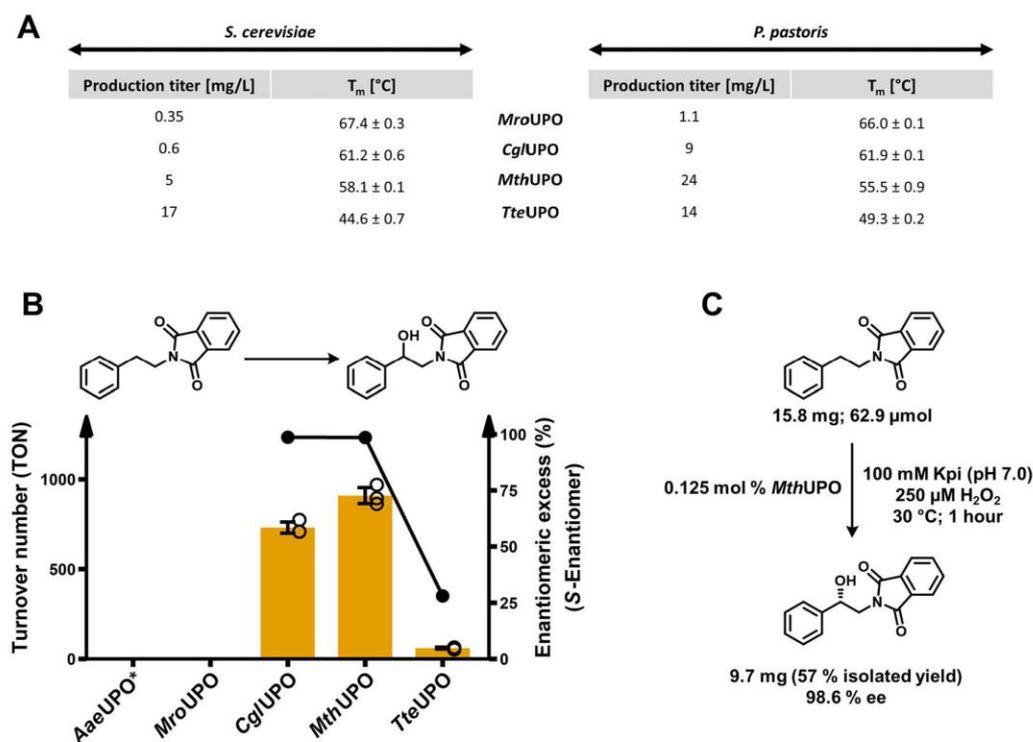

Fig. 5 Expression yields and thermostabilities of UPOs derived from the different yeast systems and conversion of a phenethylamine derivative on analytical and preparative scale. **A** Comparison of volumetric production titre of recombinant UPOs in shake flask scale (1L) between *S. cerevisiae* (episomal construct) and *P. pastoris* (integrative construct) as obtained after ultrafiltration of the respective culture supernatant. UPOs were produced and secreted utilising their natural signal peptide (*MroUPO* and *CglUPO*) or a previously identified suitable exogenous signal peptide *MthUPO* (*Sce-α* Galactosidase) and *TteUPO* (*S. cerevisiae*: *Cci-UPO*; *P. pastoris*: *Sce-Prepro*). For all *P. pastoris* production setups the methanol inducible promoter P_{CAT1} was utilised. Thermal denaturation midpoints (T_m) for the four UPOs produced in both organisms were determined in biological triplicates using purified protein samples (in 100 mM potassium phosphate; pH 7.0) using differential scanning fluorimetry (DSF). **B** Bar chart showing turnover number within one hour for the benzylic hydroxylation of *N*-phthaloyl-phenethylamine by *P. pastoris* produced *AaeUPO**, *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO*. Turnover data are mean ± s.d. of measurements made in triplicates. TON determined by GC-MS and ee% by chiral HPLC (Supplementary Figs. 18–20). **C** Preparative scale conversion of *N*-phthalimide protected phenethylamine using *P. pastoris* produced *MthUPO*.

217 mg/L for *AaeUPO**¹⁵. All proteins were purified using the attached TwinStrep-tag and analysed by SDS-PAGE (Supplementary Fig. 14). Highly pure enzyme preparations were obtained after one-step TwinStrep purification. Based on the successful production in both organisms, thermostability values (denaturation midpoint; T_m) of the four UPOs were assessed using differential scanning fluorimetry (Fig. 5A). The obtained values of the respective UPOs derived from both organisms proved to be alike to a variation of 0.7 to 4.7 °C. The highest thermostability values were obtained for *MroUPO* with 67.4 and 66.0 °C produced by *S. cerevisiae* and *P. pastoris*, respectively. The two UPOs derived from thermophilic fungi, *MthUPO* and *TteUPO*, exhibited no superior thermostability when compared to the closest related enzyme *CglUPO*. *TteUPO* revealed the lowest thermostability in the tested group with 44.6 and 49.3 °C for *S. cerevisiae* and *P. pastoris*, respectively.

Enantioselective hydroxylation of an *N*-protected phenethylamine on a preparative scale. To gain insights into the ability of the enzymes to convert industrially relevant molecules in an enantioselective manner, we selected *N*-protected phenethylamine as a substrate. The hydroxylation of phenethylamine derivatives at the benzylic position provides access to a plethora of pharmaceutically important classes like beta-blockers and sympathomimetics⁵⁴.

The peroxygenases *AaeUPO**, *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO* were produced in *P. pastoris*, purified, and assessed for their activity on *N*-phthaloyl-phenethylamine. *AaeUPO** and *MroUPO* exhibited no formation of the benzylic alcohol product, and *TteUPO* performed 60 TON within an hour while achieving an enantioselectivity of 28% ee (Fig. 5B, Supplementary Figs. 18 and 20). *CglUPO* and *MthUPO* revealed the highest activities with 730 and 908 TON, respectively, within the 1 h reaction setup (Supplementary Fig. 18). *MthUPO* showed an over-oxidation to the ketone amounting to 222 TON (Supplementary Fig. 19). The enantioselectivity of alcohol formation proved to be excellent for *CglUPO* and *MthUPO* with 98.7% ee and 98.6% ee (Supplementary Fig. 20).

Harnessing the high production titre of *MthUPO* in *P. pastoris* (24 mg/L) in combination with the previously observed good substrate conversion and high enantioselectivity we aimed for the proof-of-concept enantioselective synthesis of (S)-(+)-2-*N*-Phthaloyl-1-phenylethanol on a preparative scale (Fig. 5C). In a first upscaling reaction (300 mL total volume) 0.125 mol% of *MthUPO* derived without further purification from concentrated *P. pastoris* supernatant were used as catalyst loading. The upscaled reaction (30 °C; 1 h) led to the synthesis of 9.70 mg (S)-(+)-2-*N*-Phthaloyl-1-phenylethanol (57% purified yield) and an enantiomeric excess of 98.6% (Supplementary Fig. 20).

Discussion

Fungal unspecific peroxygenases (UPOs) have gained substantial interest as versatile hydroxylation catalyst since their initial discovery 16 years ago². The most significant limitation for the wider application of UPOs arguably remains their heterologous production utilising a fast-growing host. Thus far, only one UPO could be produced and engineered within a system amenable to high throughput: the *S. cerevisiae* secretion variant *AaeUPO**¹⁰.

Building on the therein developed expression setup, we started our endeavour to construct a versatile UPO secretion system. The constructed Golden Gate-based platform consists of a signal peptide library (Module 1), UPO genes (Module 2) and protein-tags (Module 3). This format enabled the first report of successful yeast secretion of six UPOs—two of them (*MthUPO* and *TteUPO*) derived from genome and secretome data had not been characterised as UPOs before⁴³. The whole expression platform could be subsequently transferred to *P. pastoris*, resulting in excellent UPO expression yields allowing for preparative scale hydroxylation reactions.

Since the only enzyme out of the panel that could not be produced (*CciUPO*) belongs to the group of long-type UPOs, and it previously took considerable effort to engineer the long-type UPO *AaeUPO* towards secretion in yeast, one could argue that the heterologous production of long-type UPOs seems to be more challenging¹⁰. In fact, *MroUPO*, *CglUPO*, *MthUPO* and *TteUPO*, which could be initially produced as non-engineered wild-type enzymes in yeast and characterised within the scope of this work, all belong to the class of short-type UPOs. Recent work in our laboratory suggests that gene shuffling of long-type UPOs can offer a viable option to obtain a library of active and structurally diverse long-type UPOs expanding the panel of available recombinant peroxygenases⁵⁵.

The hypothesised pivotal role of the employed signal peptides for the successful secretion of UPOs was manifested within this study. Yeast secretion signal peptides generally consist of three main parts: (1) an *N*-terminal positively charged domain, (2) a hydrophobic core and (3) a cleavage site region exhibiting mostly uncharged residues⁵⁶. The length and amino acid composition of the signal peptides, however, can vary substantially. This variation is also reflected by the selected, diverse signal peptide pool in the present paper, which ranges from several predicted and reported UPO signal peptides, commonly utilised endogenous *S. cerevisiae* signal peptides up to human (*Hsa*-Serum Albumin) and bird-derived (*Gga*-Lysozym) sequences. This set includes peptides ranging from 17 to 87 amino acids in lengths and exhibits substantial sequence alterations to provide a high diversity. Apart from the UPO-derived signal peptides, this signal peptide pool was selected based on previous reports on recombinant protein secretion in *S. cerevisiae*^{56,57}. In case of *AaeUPO** the native signal peptide was evolved by means of MORPHING³⁶ resulting in a 27-fold increased total secretion through addition of the four mutations F12Y/A14V/R15G/A21D¹⁰.

Exchanging this evolved signal peptide sequence with the corresponding *Gma*-UPO sequence resulted in a further 2.2-fold improved secretion in *S. cerevisiae* and even 6-fold enhancement in *P. pastoris*. The signal peptides *Aae*-UPO* and *Gma*-UPO display a high sequence identity and similarity of 50 and 73%, respectively. *Gma*-UPO exhibits two additional amino acids, and these insertions are the two hydrophobic amino acids alanine and leucine before position 12. These amino acid additions might be pivotal for the increased secretion level. Interestingly, the overall suitability of other signal peptides based on specific enzyme activity proved to be low (Fig. 1C), even though in many cases comparable split-GFP values were obtained when comparing respective signal peptides to the evolved *Aae*-UPO* signal peptide. This low promiscuity towards functional signal peptides points towards the occurrence

of differing *N*-termini of the mature enzyme. A hypothesis, that has been indirectly stated before in the context of this evolved enzyme⁵⁸ as introduced mutations within the mature protein (V57A and V75I) are argued to preserve the natural *N*-terminus (EPGLPPGPL) of the mature protein when produced in yeast in connection with the evolved signal peptide. This is contrary to the wild type *AaeUPO* enzyme, where *N*-terminal proteolysis (EPG↓LPPPGPL) occurs⁵⁹. Using the *Gma*-UPO signal peptide for production, we could verify the natural *N*-terminus occurrence (starting AEPGLPP) by peptide analysis (Supplementary Table 8); therefore the cleavage pattern of this signal peptide in yeast seems to be comparable to the evolved signal peptide used in previous studies^{10,13,15,58,60}. The hypothesis of low promiscuity also holds in the episomal production attempts in *P. pastoris*, where all identified active constructs exhibited the signal peptide *Aae*-UPO* or *Gma*-UPO, respectively.

The case of *Aae*-UPO* might suggest that the closest related signal peptide in terms of sequence and length demonstrates the highest secretion rates. Regarding *MthUPO* this only might be true in terms of sequence length. The wild-type signal peptide consists of 17 amino acids, and the most suitable orthologous SPs have a similar length: *Sce*- α Galactosidase (19 aa), *Ani*- α Amylase (20 aa) and *Sce*-Acid Phosphatase (18 aa). However, the sequence similarity of the most suitable signal peptides *Sce*- α Galactosidase and *Ani*- α Amylase is solely 3 and 29%, respectively. In general, a high promiscuity of *MthUPO* towards a diverse set of signal peptides was observed, leading to the identification of five (*S. cerevisiae*) and eight (*P. pastoris*) suitable signal peptides (Supplemental Figs. 5 and 12). In case of *TteUPO*, no wild-type signal peptide was retrieved, and this UPO proved to be highly promiscuous, showing no preference for a signal peptide length (17–87 amino acids) or sequence composition whatsoever. Out of the pool of 17 signal peptides, nine proved to be highly suitable (Supplementary Figs. 6 and 13), when probing *S. cerevisiae* and *P. pastoris*.

The subsequent transfer of beneficial signal peptide-gene combination to *Pichia pastoris* proved successful. Nonetheless, subtle differences and preferences were shown by a signal peptide shuffling approach for *MthUPO* and *TteUPO* in *P. pastoris*. Interestingly, the α -factor leader signal peptide (*Sce*-Prepro), which is often used as a gold standard signal peptide for target protein secretion in *P. pastoris*^{45,46}, was only identified among the top hits in combination with *TteUPO*.

In summary almost all the 17 tested signal peptides proved to be highly functional in combination with at least one UPO gene. However, predicting a suitable signal peptide for recombinant protein secretion remains challenging. Previous work reported on the engineering of improved signal peptides by means of directed evolution to produce UPOs¹⁰, laccases¹⁹, aryl-alcohol oxidases²¹ and single-chain antibodies¹⁸ in *S. cerevisiae*. These improvements seem to be highly dependent on the attached protein and are therefore not per se applicable to other non-related proteins. Novel approaches such as machine learning-based design of signal peptides might help to rationalise the use of SPs, but still need to be transferred to eukaryotic systems⁶¹. We therefore decided to build a rather diverse signal peptide panel, which can be rapidly assembled using the modular Golden Gate system and tested in a high-throughput manner in a 96-well plate setup. By employing our envisioned modular signal peptide shuffling system, we were able to further improve the production of previously described UPOs (*AaeUPO**) and obtain multiple suitable signal peptide-gene combinations to produce novel wild-type UPOs (*MthUPO* and *TteUPO*).

The GFP11 detection tag proved to be an indispensable asset to distinguish secretion from activity³⁵. Between different UPOs, the variation in fluorescence could be further pronounced based on

different accessibilities of the split-GFP-tag. This tendency was shown for *AaeUPO** where the TwinStrep-GFP11 tag (59 amino acids) yielded a 4-fold increased signal intensity relative to the shorter GFP11 tag (27 amino acids). In some cases, like *CglUPO* (Fig. 2A), the fluorescence response greatly differed from the activity depending on the employed signal peptide. This observation might be explained by different cleavage patterns at the N-terminus depending on the respective signal peptide leading to slightly altered overall folds and structures and hence activities of the mature enzyme. In the case of *CglUPO*, this hypothesis was strengthened by the occurrence of multiple SDS-Gel bands after enzymatic deglycosylation suggesting multiple patterns of signal peptide cleavages (Supplementary Fig. 8).

In the case of *AaeUPO** the substrate entrance is among other motifs substantially shaped by the C-terminal helix/loop region, which also contains a crucial stabilising C278-C319 disulfide linkage⁵⁸. Therefore, the attachment of a protein tag to the C-terminus, which we performed in all setups based on the modular design, might be detrimental to the activity. Indeed, using an *AaeUPO** construct without the C-terminal tag resulted in an improved UPO activity by approx. 40% (Supplementary Fig. 4). The successful placement of an N-terminal tag rather than a C-terminal-modification, however, is challenging. This difficulty is due to the varying cleavage patterns at the N-terminus of the secreted proteins (see above) and also an extra Golden Gate module would be required (signal peptide - N-tag - gene) to preserve the compatibility of the system. Testing an N-terminal Strep II tag resulted in a nearly complete loss of activity (−95%) within the 96 well screening setup (Supplementary Fig. 4). Although a decreased activity is detrimental to the discovery and engineering of enzymes, the observed loss (−40%) when attaching a C-terminal tag is still tolerable, as the split-GFP signal would even in case of a loss of activity provide the signal of successful secretion and allow further enzyme characterisation. To overcome possible limitations, we constructed an additional C-terminal tag module (pAGM9121_TEV-His-GFP11), which includes a TEV protease cleavage site located in front of the His₆-GFP11 detection and purification tag, thereby enabling the removal of the C-terminal appendix after purification and prior to activity measurements.

The utilisation of the GFP11-tag also led to the discovery and verification by subsequent peptide analysis of the peroxygenases *GmaUPO* and *MweUPO*—even though no enzymatic activity could be determined. Repeated shake flask production attempts in *S. cerevisiae* and *P. pastoris* did not lead to any specific absorption spectra (native and CO differential spectra) or activities. This points towards occurring problems such as extremely low secretion rates, incorrect haem incorporation or protein misfolding.

The adaptation to episomal plasmid expression in *P. pastoris* proved that the entire modular signal peptide shuffling system could be readily transferred to another yeast organism. The applicability in *P. pastoris* furthermore paves the way towards future-directed evolution enterprises entirely performed in *P. pastoris*, further streamlining the workflow from gene discovery to construct identification and large-scale protein production. In comparison to the *S. cerevisiae*-based episomal system, the *P. pastoris*-based episomal plasmid expression of *MthUPO* retained 60% of the activity (Fig. 4E). However, there is still plenty of potential for *P. pastoris* production optimisation utilising different promoters, carbon sources, induction and co-feeding strategies^{50,62}. A substantial synergistic influence of the promoter–signal peptide combination was observed, as underlined for *TteUPO* in Fig. 4D. This observation represents an aspect that should be further investigated in detail, for example, by expanding the modular system, including an additional shuffling module for a set of promoters to achieve simultaneous signal

peptide and promoter shuffling. Production of *MthUPO* utilising the integrative plasmid led to substantially improved production when compared to the episomal counterpart. Nevertheless, the obtained interclonal variation within the integrative system is substantial, rendering the episomal plasmid expression more suitable for performing reliable high-throughput endeavours (Fig. 4C). In the case of *MthUPO*, we observed a diminished split-GFP response compared to the respective *S. cerevisiae* construct, which might be explained through differing glycosylation patterns, as observed by SDS Gel analysis (Supplementary Figs. 8 and 14). We hypothesise that this heterogeneous glycosylation pattern might mask the C-terminal protein tag within a proportion of enzymes in a greater extent than *S. cerevisiae*, thus impeding successful interaction with the GFP 1–10 counter fragment for GFP reconstruction. Also, the removal of the C-terminal tag by endogenous proteases is a possible scenario.

UPOs have been reported to be homologously produced over the course of several weeks in bioreactors to yield *AaeUPO*, *CraUPO* (*Coprinus radians*), *CglUPO* and *MroUPO* in production titres of 9 mg/L², 19 mg/L⁶³, 40 mg/L⁹ and 445 mg/L⁴¹, respectively. Besides the time-consuming production, only the wild-type enzyme can be produced, and the overall recovery of pure protein after several purification steps are reported to be below 20%^{2,41,63}. Using a heterologous yeast expression system in a shake flask format, the highest reported production titres are obtained with the engineered *AaeUPO** in *S. cerevisiae* and *P. pastoris* (each 8 mg/L)^{10,15}.

The newly discovered peroxygenases *TteUPO* displayed unprecedented UPO expression titres in *S. cerevisiae* of 17 mg/L in *S. cerevisiae*. *MthUPO* revealed a good production titre in *S. cerevisiae* (5 mg/L) and after transfer to *P. pastoris* the overall highest expression yields in *P. pastoris* with 24 mg/L could be achieved. Additionally, we could acquire high recovery of highly pure protein after one-step TwinStrep-based affinity purification^{38,40} (Supplementary Figs. 8 and 14).

To compare the results of the bioconversion setups to literature-derived data, in all experiments the secretion variant *AaeUPO** was included, which exhibits comparable catalytic properties to the fungal wild-type enzyme *AaeUPO* and therefore allows the comparison with previously obtained analysis in the literature¹⁰. As there are no data available for the homologously expressed *MthUPO*, *TteUPO* and *CglUPO*, this setup was the best way to allow comparative analysis of enzymatic performances in previous heterologous and homologous setups.

The relevance of expanding the set of recombinant UPOs is reflected by the fact that *CglUPO*, *MthUPO* and *TteUPO* displayed a different substrate specificity when compared to *AaeUPO** (Fig. 3). When testing the conversion of naphthalene within our reaction setup, *AaeUPO** showed the highest activities with TONs of 2950, yielding 92% of 1-naphthol and generally low overoxidation to para-naphthoquinone. This 1-naphthol to naphthoquinone product distribution is in accordance with previously obtained data⁶⁰. *CglUPO*, *TteUPO* and *MthUPO* showed lowered TONs between 720 and 1260 for 1-naphthol formation and an elevated ratio of 49–55% of the naphthoquinone product. This work on *MthUPO* catalysed naphthalene oxidation was recently expanded by performing protein engineering and testing a range of naphthalene derivatives⁶⁴.

The epoxidation experiments of styrene using *AaeUPO** led in our setup to 4580 TONs and a 2% *ee*.

Previously reported data for *AaeUPO* revealed up to 10000 TONs with 4.6% *ee* when using a light-driven in situ hydrogen peroxide formation⁶⁵. Combining *AaeUPO** and tert-butylhydroperoxide added via a syringe pump setup resulted in 3200 TONs and 12% *ee*⁶⁶. Within our setup, when using *CglUPO* similar epoxidation activities with TONs of 4120 were obtained.

Most interestingly, *Mro*UPO, *Cgl*UPO and *Mth*UPO exhibited substantially higher enantioselectivities of 30, 44 and 45 % *ee*, respectively, than the reported data for *Aae*UPO and *Aae*UPO*. This indicates differences in the active site geometry of the diverse UPO set and therefore provides an interesting point for further protein engineering towards higher stereoselectivities of styrene epoxidations.

For the benzylic hydroxylation of the homologous phenylalkane row, ranging from phenylethane to phenylpentane *Aae*UPO* displayed the highest activities and selectivities using phenylethane (4540, 98% *ee*) and phenylpropane (1670, 99% *ee*) as substrates, but only traces of product for benzylic hydroxylation of phenylbutane and phenylpentane. Wild-type *Aae*UPO was previously reported to achieve TONs of 10600 and 7100 for phenylethane and phenylpropane, respectively, and excellent selectivities (>99% *ee*) in both cases⁶⁷. Additionally, verifying the observed negative tendency of decreasing benzylic hydroxylation activity for increasing alkyl chain length *Aae*UPO* in combination with an enzymatic cascade for the in situ production of hydrogen peroxide even led up to 294700 TONs¹.

The enzymes *Cgl*UPO, *Mth*UPO and *Tte*UPO showed an opposite selectivity when compared to *Aae*UPO* regarding benzylic hydroxylation and displayed the lowest activities for phenylethane and highest for phenylbutane and -pentane conversion, respectively. *Tte*UPO furthermore catalyses the formation of the opposite alcohol enantiomer (S) compared to the other enzymes for the conversion of phenylpropane to phenylbutane.

Good activities and excellent enantioselectivities could also be achieved when challenging the enzymes for the benzylic hydroxylation of *N*-phthalimide protected phenethylamine in case of the enzymes *Cgl*UPO and *Mth*UPO. This observation is vastly different from *Aae*UPO*, displaying no product formation and no known enantioselective conversion of substrates of similar structure.

The high UPO production yields in *P. pastoris* of *Mth*UPO enabled a proof-of-concept approach to yield the chiral alcohol product on the preparative scale with a challenging phenethylamine derivative and yielded 57% yield and 98.6% *ee*. The direct benzylic hydroxylation of phenethylamine compounds was previously reported for copper-dependent dopamine *b*-hydroxylases (DbH), but not on a preparative scale^{68,69}. As DbHs suffer from difficult expression, their engineering towards similar substrates and higher activities is currently hampered.

To allow other researchers to harness the modular yeast system, we deposited all relevant plasmids (signal peptides, protein tags and expression plasmids) as a kit with the non-profit plasmid repository Addgene called *Yeast Secrete and Detect* Kit (Kit # 1000000166). The herein developed overall workflow for functional UPO secretion and detection can be performed within a minimal period of 15 days (Supplementary Fig. 2). Within this period, beneficial episomal constructs are identified in a 96-well high throughput system, exploiting activity measurements and protein quantification by the split-GFP assay^{34,35}. Identified constructs can then be directly used for upscaling to shake flasks, one-step affinity target protein purification and subsequent bio-conversion testing.

In summary, the obtained data of this study proves that the built workflow starting from a putative UPO gene, followed by identification of suitable expression constructs via signal peptide shuffling in combination with high-throughput screening in *S. cerevisiae* as well as *P. pastoris* and subsequent production upscaling can lead to highly enantioselective preparative product formations of pharmaceutically valuable building blocks.

In the future, this workflow could be applied to other UPO genes or generally genes of interest, which are suitable for production in yeast, especially for proteins that might require

efficient post-translational modifications such as glycosylation and disulfide linkage. Besides target protein secretion, the constructed expression plasmids also allow for intracellular production when no signal peptide is attached. During the submission and revision process of this publication, two papers demonstrated the engineering of *Mth*UPO using the herein developed *S. cerevisiae* setup^{64,70} and one publication expanded the episomal *P. pastoris* system to a range of promoters and new UPO enzymes⁷¹.

Methods

Chemicals. Solvents were used as received without further purification. Ethyl acetate and acetone were utilised in GC ultra-grade (≥99.9%) from Carl Roth (Karlsruhe, DE). Acetonitrile was purchased from Merck (Darmstadt, DE) in gradient grade for LC (≥99.9%). Deuterated solvents for NMR spectroscopy were purchased from Deutero (Kastellaun, DE). All further reaction chemicals were purchased either from Sigma-Aldrich (Hamburg, DE), TCI Chemicals (Tokyo, JP), Merck (Darmstadt, DE), abcr (Karlsruhe, DE) or Fluka Chemika (Buchs, CH) and used as received.

Enzymes and cultivation media. For cultivation of *E. coli* cells terrific broth (TB) media from Carl Roth (Karlsruhe, DE) was used. For cultivation of *S. cerevisiae* cells D-Galactose, Peptone and Synthetic Complete Mixture (Kaiser) Drop-Out (-URA) were purchased from Formedium (Hunstanton, GB). Yeast nitrogen base (without amino acids) and Yeast extract were purchased from Carl Roth (Karlsruhe, DE). For *P. pastoris* cultivation methanol (99.9% Chromasolv purity grade) purchased from Honeywell Chemicals (Seelze, DE) was used as additional carbon source. PNGaseF and BsaI were purchased from New England Biolabs (Ipswich, US). BbsI and FastDigest AseI were purchased from ThermoFisherScientific (Waltham, US) and T4 DNA Ligase from Promega (Madison, US).

Oligonucleotides and gene parts. All oligonucleotides were purchased in the lowest purification grade “desalted” and minimal quantity at Eurofins Genomics (Ebersberg, DE). The *Pichia pastoris* CAT1 promoter was purchased as a gene part from Twist Bioscience (San Francisco, US). The genes of the *Aae*UPO variant *Aae*UPO*, *Gma*UPO, *Mwe*UPO and the sfGFP 1-10 gene were purchased as plasmid-cloned genes from Eurofins Genomics (Ebersberg, DE). The genes of *Cgl*UPO, *Mth*UPO and *Tte*UPO were retrieved as codon-optimised (*S. cerevisiae* codon usage) gene strands from Eurofins Genomics.

Expression plasmid construction for *S. cerevisiae*. A Level 1 Golden Gate-based shuttle expression plasmid was constructed using a pAGT572 plasmid as backbone structure⁷², which can be propagated in *E. coli* and *S. cerevisiae*. It enables antibiotic selection (Ampicillin resistance) and yeast auxotrophy selection (URA3 marker). To enable expression of a target gene a Gal 1.3 Promoter—a truncated, modified version of the widespread GAL1 Promoter—is integrated upstream and a strong DIT1 terminator downstream of the cloning acceptor site. As placeholder for a target gene sequence a lacZ cassette (approx. 600 bp) is integrated, which enables β-galactosidase-based blue/white selection of transformants based on the conversion of X-Gal. Upon digestion with BsaI the lacZ cassette is released, and a fitting open reading can be integrated in frame (e.g. Signal Peptide-GenC-terminal Tag) into the plasmid, thereby reconstituting a fully functional expression plasmid. The constructed expression plasmid was coined pAGT572_Nemo_2.0. Using the pAGT572 plasmid backbone and the GAL1 Promoter as units a second expression plasmid coined pAGT572_Nemo was constructed that follows the same functionality and principle but exhibits the original GAL1 promoter.

Expression plasmid construction for *Pichia pastoris*. Two level 1 Golden Gate-based shuttle expression plasmids were constructed, which can be propagated in *E. coli* (Amp^R) as well as *P. pastoris* (Hygromycin B^R). To enable episomal plasmid propagation in *P. pastoris*, the plasmids were equipped with a previously described functional ARS sequence^{47,73}, which was PCR amplified from *Kluyveromyces lactis* genomic DNA. The plasmids exhibit the strong constitutive GAP promoter (pPAP001) or the strong methanol inducible promoter CAT1 (pPAP002), both in combination with a strong GAP terminator (tGAP). As placeholder for a target gene sequence, a lacZ cassette is used. For the stable integration of transcription units into the *P. pastoris* genome, a third universal integrative plasmid (pPAP003) was designed. A shuttle plasmid was constructed, which can be propagated in *E. coli* (Kanamycin^R) as well as *P. pastoris* (Hygromycin^R). As placeholder for a target transcription unit a lacZ cassette is integrated. Upon digestion with BbsI the lacZ cassette is released and a fitting transcription unit (Promoter- ORF- Terminator) can be integrated (derived from respective pPAP001 and pPAP002 episomal plasmids as donors) into the plasmid, thereby reconstituting a fully functional integration plasmid. Several parts (GAP promoter, GAP terminator, AOX integration marker and Hygromycin B resistance marker) of the constructed plasmids

were PCR amplified and derived from a previously introduced Golden Gate based *P. pastoris* assembly system, coined GoldenPiCS⁴⁴.

Golden Gate cloning of Level 0 standard parts.

All genetic parts were cloned as individual Level 0 standard modules into the universal Level 0 acceptor plasmid pAGM9121 (Spectinomycin^R). Therefore, three functional units were pre-defined: (a) signal peptide (contains start codon); (b) gene (lacking start and stop codon) and (c) C-terminal Protein-tag (contains stop codon). 4 bp sticky overhangs that are released upon Type II s enzyme treatment (BsaI and BbsI) and guide subsequently a correct reassembly were chosen accordingly to the nomenclature of gene assembly as described within the ModularCloning (MoClo) system³³. An overview of the reassembly concept is provided in Supplementary Fig. 1. For the cloning of the individual modules suitable oligonucleotides were designed to allow for cloning into pAGM9121. Primers followed a general scheme (Supplementary Fig. 1). Fragments were amplified by PCR from a suitable template sequence or generated by hybridisation of two complementary oligonucleotides. PCR products were analysed as small aliquot (5 µL) by agarose gel electrophoresis for occurrence of the expected size and the remaining sample subsequently recovered and purified using a NucleoSpin[®] Gel and PCR Clean-up Kit (Macherey-Nagel, Düren, DE). Golden Gate reactions were performed in a total volume of 15 µL. The final reaction volume contained 1-fold concentrated T4 ligase buffer (Promega, Madison, US). Prepared reaction mixtures containing ligase buffer, acceptor plasmid (20 fmol) and the corresponding insert (20 fmol) was adjusted to 13.5 µL with ddH₂O. In a final step, the corresponding enzymes were quickly added. First, a volume of 0.5 µL of the respective restriction enzyme BbsI (5 units/µL) was added and then 1 µL (1–3 units/µL) of T4 ligase. Golden Gate reactions were performed for 3 h (37 °C) and concluded by an additional enzyme inactivation step (80 °C; 20 min). The whole Golden Gate reaction volume was used to transform chemically competent *E. coli* DH10B cells. After heat shock transformation and recovery, the mixture was plated in different quantities on selective LB Agar plates (50 µg × mL⁻¹ X-Gal; 100 µg × mL⁻¹ Spectinomycin; 150 µM IPTG). Based on the occurrence of the lacZ selection marker one can easily distinguish between white colonies (recombined plasmid) and empty plasmid (blue). In general, the described protocol led to several thousand recombinant colonies with a nearly absolute proportion (>99%) of recombined, white colonies. Single colonies were checked for correct insert sizes by means of colony PCR (pAGM9121 sequencing primer; Supplementary Table 1). Positively identified clones were inoculated into 4 mL of TB-Medium (100 µg × mL⁻¹ Spectinomycin) and corresponding plasmid DNA prepared (NucleoSpin Plasmid Kit (Macherey-Nagel, Düren, DE)). After verification of the correct, intended insert sequence by Sanger Sequencing (Eurofins Genomics, Ebersbach, DE) respective plasmids were included for further use within the modular Golden Gate cloning approaches.

Golden Gate cloning of expression plasmids. The expression plasmids (*S. cerevisiae*: pAGT572_Nemo and pAGT572_Nemo 2.0; *P. pastoris*: pPAP001 and pPAP002) were used as respective acceptor plasmid for the assembly of the individual tripartite open reading frames (5' Signal Peptide-Gene-C-terminal Tag 3'). The individual parts were thereby derived as parts from standard level 0 plasmids (pAGM9121 backbone), which can be released from the pAGM9121 backbone upon BsaI restriction digest. Golden Gate reactions were performed in a total volume of 15 µL. The final reaction volume contained 1-fold concentrated T4 ligase buffer. Prepared reaction mixtures containing ligase buffer, the acceptor plasmid (20 fmol) and the corresponding inserts as level 0 modules (Signal Peptide, Gene, C-terminal Tag) were added to 20 fmol each and the overall volume adjusted to 13.5 µL with ddH₂O. In the case of a signal peptide shuffling approach 17 different pAGM9121-Signal Peptide combinations were added in equimolar ratios (1.2 fmol each). In a final step, the corresponding enzymes were quickly added. First, a volume of 0.5 µL of the restriction enzyme BsaI (10 units/µL) was added and then 1 µL (1–3 units/µL) of T4 ligase. Golden Gate reactions were performed using a temperature cycling program (50x passes) between 37 °C (2 min) and 16 °C (5 min) and concluded by an additional enzyme inactivation step (80 °C; 20 min). The whole Golden Gate reaction volume was used to transform chemically competent *E. coli* DH10B cells. After heat shock transformation and recovery the mixture (approx. 320 µL) was split into two fractions, 50 µL were plated on selective LB Agar plates (+ X-Gal; 100 µg × mL⁻¹ Ampicillin; + IPTG) and the remaining volume used to directly inoculate 4 mL TB Medium (+ Amp) to preserve the genetic diversity of the shuffling library. The following day the success of the Golden Gate reaction was evaluated based on the performed blue/white screening, discriminating the empty plasmid (lacZ; blue) from recombined, white colonies. In general, the described protocol for ORF assembly and signal peptide shuffling as special case led to several hundred recombinant colonies with a high proportion (>90%) of recombined, white colonies. In the case of single defined, "unshuffled" constructs single colonies were checked for correct insert sizes by means of colony PCR (using respective plasmid sequencing primer). Positively identified clones were inoculated into 4 mL of TB-Medium (+Amp) and corresponding plasmid DNA prepared (NucleoSpin Plasmid Kit (Macherey-Nagel, Düren, DE)). In the case of shuffled signal peptide constructs, plasmid DNA was prepared as a library by direct inoculation of the transformation mixture into the liquid culture and subsequent DNA isolation (see above).

Plasmid transformation into *S. cerevisiae*. Respective single plasmids or plasmid mixtures (pAGT572_Nemo or pAGT572_Nemo 2.0 backbone) were used to transform chemically competent *S. cerevisiae* cells (INVSc1 strain) by polyethylene glycol/lithium acetate transformation. INVSc1 cells were prepared and stored at -80 °C in transformation buffer (15% (v/v) glycerol; 100 mM lithium acetate; 500 µM EDTA; 5 mM Tris-HCl pH 7.4) as 60 µL aliquots until usage. For transformation, an amount of 100 ng of the plasmid preparation was added to 10 µL of lachssperm DNA (10 mg/mL; Sigma Aldrich, Hamburg, DE) and mixed. This mixture was then added to a thawed aliquot of INVSc1 cells on ice. 600 µL of transformation buffer (40% (v/v) polyethylene glycol 4000; 100 mM lithium acetate; 1 mM EDTA; 10 mM Tris-HCl pH 7.4) were added and the cells incubated under rigid shaking (30 °C; 850 rpm) for 30 min. Afterwards, 70 µL of pure DMSO was added and the cells incubated for a further 15 min at 42 °C without shaking. Finally, the cells were precipitated by short centrifugation, the supernatant discarded, and the cell pellet resuspended in 350 µL sterile ddH₂O. Different volumes were plated on Synthetic Complement (SC) Drop Out plates supplemented with 2% (w/v) glucose as carbon source and lacking Uracil as an auxotrophic selection marker. Plates were incubated for at least 48 h at 30 °C till clearly background distinguishable white colonies appeared.

Plasmid transformation into *P. pastoris*. Respective single plasmids or plasmid mixtures (pPAP001 or pPAP002 backbone) were used to transform *P. pastoris* cells (X-33 strain) by means of electroporation. Electrocompetent X-33 cells were prepared according to a condensed transformation protocol for *P. pastoris*⁷⁴. Cells were stored in BEDS solution (10 mM bicine-NaOH pH 8.3, 3% (v/v) ethylene glycol, 5% (v/v) DMSO and 1 M sorbitol) as 60 µL aliquots (-80 °C) till further use. For the transformation of episomal plasmids 20 ng of the circular plasmid were added to one aliquot of thawed competent X-33 cells. The cell-plasmid mix was transferred to an electroporation cuvette (2 mm gap) and cooled for 10 min on ice prior to the transformation. Electroporation was performed using a Micropulser Device (Bio-Rad, Hercules, US) and using manual implemented, standardised settings (1.5 kV, 1 pulse) for all transformation setups, leading to a general pulse interval of 5.4–5.7 ms. Immediately after electroporation cells were recovered in 1 mL of ice-cold YPD-Sorbitol solution (10 g/L peptone, 5 g/L yeast extract, 500 mM sorbitol), transferred to a new reaction tube and incubated for one hour under rigid shaking (30 °C, 900 rpm) in a Thermomix device (Eppendorf, Hamburg, DE). After incubation, cells were precipitated by centrifugation (5700 rpm, 5 min). The supernatant was discarded, and the cells resuspended in 200 µL of fresh YPD medium. 100 µL of the suspension was then plated on selective YPD Agar plates supplemented with 150 µg/mL Hygromycin B. Plates were incubated at 30 °C for at least 48 h till clearly visible colonies appeared. In general, the described setup led to the occurrence of several hundred colonies per plate. For the transformation of integrative plasmids (pPAP003 backbone) the setup was slightly modified as linearised plasmid is used for transformation. Therefore, previously prepared circular plasmid DNA was digested with AseI (Isochizomer: SgsI). 2.5 µg of the respective plasmid DNA were mixed with 3 µL of 10x fold FastDigest Buffer, the volume adjusted to 29.5 µL using ddH₂O and in the last step, 0.5 µL of FastDigest SgsI added. Digestion was performed overnight (16 h, 37 °C) and terminated by an enzyme inactivation step (20 min, 80 °C). Linearised plasmid DNA was then subsequently prepared according to the manufacturer instruction using a NucleoSpin[®] Gel and PCR clean up Kit (Macherey-Nagel, Düren, DE). The transformation of *P. pastoris* was performed in a congruent manner as described before, except for using 100 ng linearised plasmid for transformation, since the overall transformation efficiency is substantially reduced in comparison to the transformation of the circular, episomal plasmid.

Microtiter plate cultivation of *S. cerevisiae*. For peroxygenase production in microtiter plate format specialised 96 half-deep well plates were utilised. The model type CR1496c was purchased from EnzyScreen (Heemstede, NL) and plates were covered with fitting CR1396b Sandwich cover for cultivation. Plates and covers were flushed before every experiment thoroughly with 70% ethanol and air-dried under a sterile bench until usage. In each cavity, 220 µL of minimal expression medium were filled and inoculated with single, clearly separated yeast colonies using sterile toothpicks. The minimal selective expression medium (1x concentrated Synthetic complement Drop out stock solution lacking uracil; 2% (w/v) galactose; 71 mM potassium phosphate buffer pH 6.0; 3.2 mM magnesium sulfate; 3.3% (v/v) ethanol; 50 mg/L haemoglobin; 25 µg/L chloramphenicol) was freshly prepared out of sterile stock solutions immediately before each experiment, mixed and added to the cavities. After inoculation of the wells the plates were covered, mounted on CR1800 cover clamps (EnzyScreen) and incubated in a Minitor shaking incubator (Infors, Bottmingen, SU) for 72 h (30 °C; 230 rpm). After cultivation, the cells were separated from the peroxygenase containing supernatant by centrifugation (3400 rpm; 50 min; 4 °C).

Microtiter plate cultivation expression in *P. pastoris*. General experimental setup as before with *S. cerevisiae*. Each cavity was filled with 220 µL of buffered complex medium (BM) and inoculated with single, clearly separated yeast colonies using sterile toothpicks. Basic BM (20 g/L peptone; 10 g/L yeast extract; 100 mM potassium phosphate buffer pH 6.0; 1x YNB (3.4 g/L yeast nitrogen base without

amino acids; 10 g/L ammonium sulfate); 400 µg/L biotin; 3.2 mM magnesium sulfate; 25 µg/L chloramphenicol; 50 mg/L haemoglobin; 150 µg/L Hygromycin B) was freshly prepared out of sterile stock solutions immediately before each experiment, mixed and added to the cavities. Depending on the type of utilised promoter (pPAP001: P_{GAP} and pPAP002: P_{CAT1}), the BM medium was supplemented with different carbon sources for cultivation and induction, respectively. pPAP001 constructs were cultivated utilising 1.5% (w/v) of glycerol or glucose as sole carbon source. In the case of the methanol inducible CAT1 promoter, a mixed feed strategy was employed combining 0.5% (w/v) of glycerol with 1.5% (v/v) methanol. Cultivation and centrifugation was as described before for *S. cerevisiae*.

Shake flask cultivation *S. cerevisiae*. A preculture of 50 mL of SC Drop out selection media (+ 2% (w/v) raffinose and 25 µg/L chloramphenicol) was inoculated with one single colony derived from a selection plate (SC Drop; -Uracil) and grown for 48 h (30 °C; 160 rpm; 80% humidity). This incubation typically resulted in a final OD_{600nm} of approx. 12 to 13. The main expression culture was inoculated with a starting optical density of 0.3. For large-scale peroxxygenase production rich non-selective expression medium (20 g/L peptone; 10 g/L yeast extract; 2% (w/v) galactose; 71 mM potassium phosphate buffer pH 6.0; 3.2 mM magnesium sulfate; 3.3% (v/v) ethanol; 25 µg/L chloramphenicol) was utilised. Cultivation was performed in 2.5 L Ultra yield flasks (Thomson Instrument, Caltanissetta, US) in a final culture volume of 500 mL per flask after sealing the flask with breathable Aeraseal tape (Sigma Aldrich, Hamburg, DE) allowing for gas exchange. The main cultures were incubated for further 72 h (25 °C; 110 rpm; 80% humidity). After cultivation, the cells were separated from the peroxxygenase containing supernatant by centrifugation (4300 rpm; 35 min; 4 °C).

Shake flask cultivation *P. pastoris*. For the large-scale protein production using shake flasks genomically integrated single constructs (pPAP 003 backbone; integration into chromosomal 3' region of *P. pastoris* AOX1 gene) were chosen. These constructs were previously identified by screening at least 4 different colonies per individual construct within an MTP screening setup and choosing a respective production strain based on a high as possible, clearly distinguishable NBD conversion in comparison to the background control (pPAP003 empty plasmid).

Precultures were prepared in 50 mL YPD medium (+ 25 µg/L chloramphenicol) and cultivated for 48 h (30 °C; 160 rpm; 80% humidity), typically resulting in a final OD_{600nm} of approx. 17 to 19. The main expression culture was inoculated with a starting optical density of 0.3. For large-scale peroxxygenase production BM-based expression media (20 g/L peptone; 10 g/L yeast extract; 100 mM potassium phosphate buffer pH 6.0; 1x YNB (3.4 g/L yeast nitrogen base without amino acids; 10 g/L ammonium sulfate); 400 µg/L biotin; 3.2 mM magnesium sulfate; 25 µg/L chloramphenicol) was utilised. In the case of constitutively expressing GAP constructs 2% (w/v) Glucose was added (BMG media) as a carbon source for *Pichia* growth. In the case of the methanol inducible CAT1 promoter a two-phase feeding was applied, firstly inoculating the cells into BM medium (see above) supplemented with 0.5% (w/v) glycerol as carbon source. 24 h and 48 h after inoculation 0.8% (v/v) of methanol were added as an inducer of the CAT1 promoter. Cultivation and final centrifugation were performed as described for *S. cerevisiae*.

Supernatant ultrafiltration and protein purification. The supernatant was concentrated approx. 20-fold by means of ultrafiltration. Therefore, a Sartocoon Slice 200 membrane holder (Sartorius, Göttingen, DE) was equipped with a Sartocoon Slice 200 ECO Hydrosart Membrane (10 kDa nominal cut-off; Sartorius) within a self-made flow setup. The flow system for ultrafiltration was operated by an EasyLoad peristaltic pump (VWR International, Darmstadt, DE). Firstly, the cleared supernatant (1 L) was concentrated approx. 10-fold to a volume of 100 mL and 900 mL of purification binding buffer (100 mM Tris-HCl pH 8.0, 150 mM NaCl) were added as a buffer exchange step. This sample was then concentrated to a final volume of 50 mL. Protein purification was implemented utilising the C-terminal attached double Strep II Tag (WSHPQFEK), coined TwinStrep® (Iba Lifesciences, Göttingen, DE). As column material, Strep-Tactin®XT Superflow® columns (1 mL or 5 mL; Iba Lifesciences) were chosen and the flow system operated by an EasyLoad peristaltic pump (VWR). In a first step, the column was equilibrated with 5 column volumes (CVs) binding buffer. The concentrated sample (50 mL) was filter sterilised (0.2 µm syringe filter) and applied to the column with an approximate flow rate of 1 mL/min. After application, the column was washed with 7 CVs binding buffer. Elution was performed based on binding competition with biotin, therefore approx. 2 CV of elution buffer (100 mM Tris-HCl pH 8.0, 150 mM NaCl; 50 mM biotin) were applied to the column. The pooled elution fraction was then dialysed overnight (4 °C) against 5 L of storage buffer (100 mM potassium phosphate pH 7.0) using ZelluTrans dialysis tubing (6–8 kDa nominal cut-off; Carl Roth) and the recovered, dialysed sample stored at 4 °C till further use.

Plasmid preparation of episomal plasmids from yeast. Yeast plasmids of identified clones were recovered by means of digestive Zymolase cell treatment and alkaline cell lysis. Therefore, clones were inoculated and cultivated for 48 h (30 °C; 250 rpm) in 4 mL of selection medium, in case of *S. cerevisiae* SC Drop out medium (-Uracil; 2% (w/v) Glucose) was used and in the case of *P. pastoris* single colonies

were inoculated into 4 mL of YPD (+ 150 µg/mL Hygromycin) to preserve the selection pressure. After cultivation cells were pelleted by centrifugation and 1 mL of washing buffer (10 mM EDTA NaOH; pH 8.0) added and the pellet resuspended by light vortexing. Cells were subsequently pelleted (5000 ×g; 10 min) and the supernatant discarded. Afterwards, cells were resuspended in 600 µL of Sorbitol Buffer (1.2 M sorbitol, 10 mM CaCl₂, 100 mM Tris-HCl pH 7.5, 35 mM β-mercaptoethanol) and 200 units of Zymolase (Sigma Aldrich, Hamburg, DE) added followed by an incubation step for 45 min (30 °C; 800 rpm) for cell wall digestion. After incubation cells were pelleted by centrifugation (2000 ×g; 10 min) the supernatant discarded, and the plasmid preparation started with an alkaline lysis step following the manufacturer's instructions (NucleoSpin Plasmid Kit, Macherey Nagel). In the final step, yeast-derived episomal plasmids were eluted in 25 µL elution buffer (5 mM Tris-HCl pH 8.5), and the whole eluate used to transform one aliquot of *E. coli* DH10B (transformation as described above), plating the whole transformation mix on a selective LB-Agar plate (Amp^R). On the following day, single colonies were picked, inoculated into 4 mL of TB medium (+Amp), plasmid prepared and sent for Sanger Sequencing (Eurofins Genomics) to elucidate the respective sequence of the open reading frame.

Thermostability measurements. Thermostability measurements of the purified enzymes were performed by Differential Scanning fluorimetry (DSF) on a Prometheus NT.48 nanoDSF instrument (NanoTemper Technologies GmbH, München, DE) in storage buffer (100 mM Tris-HCl pH 7.0). Approximately 10 µL of sample volume were loaded into a Prometheus NT.48 High Sensitivity Capillary (NanoTemper Technologies GmbH). Protein unfolding was subsequently monitored by following the ratio of intrinsic protein tyrosine and tryptophan fluorescence at 350 nm to 330 nm over time, increasing the temperature from 20 °C to 95 °C with a heating ramp of 1 °C per minute. The melting temperature corresponds to the maximum of the first derivative of the 350/330 nm ratio. All measurements were performed at least in triplicates.

Split-GFP assay. Protein normalisation was performed employing the principle of a split GFP normalisation assay as described by Santos-Aberturas et al.³⁵ with slight modifications. The GFP fluorescence complementation fragment sfGFP 1–10 was cloned into the Golden Mutagenesis plasmid pAGM22082_cRed³² for T7 promoter controlled expression in *E. coli* (BL 21 DE3 strain). The sfGFP 1–10 fragment was prepared as an inclusion body preparation according to the previous reports³⁵. For measurement, a 96 well Nunc MaxiSorp Fluorescence plate (Thermo-FisherScientific, Waltham, US) was blocked (25 min, light shaking) with 180 µL of BSA blocking buffer (100 mM Tris-HCl pH 7.4, 100 mM NaCl, 10% (v/v) glycerol, 0.5% (w/v) BSA). The blocking solution was discarded and 20 µL of the yeast media supernatant (*S. cerevisiae* or *P. pastoris*) derived from the peroxxygenase expression plates added. A 10 mL aliquot of the sfGFP 1–10 complementation fragment (storage: –80 °C) was quickly thawed in a water bath and diluted 1x fold into ice-cold TNG buffer (100 mM Tris-HCl pH 7.4, 100 mM NaCl, 10% (v/v) glycerol) and 180 µL of this screening solution added to each well. Immediate fluorescence values (GFP fluorophore: excitation wavelength: 485 nm; emission wavelength: 535 nm; top read mode) were measured using a 96 well plate fluorescence reader Spark 10 M (TECAN, Grödig, AT), setting an empty plasmid control well as 10% of the overall signal intensity (well calculated gain). After storage of the plate for at least one up to three nights (at 4 °C) final fluorescence values were measured in a comparable manner. Protein quantities were then normalised based on the relative fluorescence increase of each respective well (differential values) and in comparison, to the empty plasmid backbone.

DMP assay. The use of 2,6-Dimethoxyphenol (DMP) as a suitable microtiter plate substrate for the measurement of peroxxygenase catalysed conversion to the colorimetric product coerulignone has been described before⁶⁰. The described conditions have been adapted with slight modifications. In brief, 20 µL of peroxxygenase containing supernatant were transferred to a transparent polypropylene 96-well screening plate (Greiner Bio-One, Kremsmünster, AT) and 180 µL of screening solution (final: 100 mM potassium phosphate pH 6.0; 3 mM 2,6-Dimethoxyphenol; 1 mM hydrogen peroxide) added. Absorption values (λ: 469 nm) of each well were immediately measured after addition in a kinetic mode (measurement interval: 30 s) over a duration of 5 min utilising the 96-well microtiter plate reader SpectraMax M5 (Molecular Devices, San José, US). Slope values of absorption increase corresponding to coerulignone formation were obtained, paying special attention to the linearity of the observed slope to obtain reliable relative DMP conversion values for comparison of the respective wells.

NBD assay. The use of 5-nitro-1,3-benzodioxole (NBD) as a suitable microtiter plate substrate for the measurement of peroxxygenase catalysed conversion to the colorimetric product 4-Nitrocatechol has been described before^{37,75}. Screening as described above for DMP but adding 180 µL of screening solution (final: 100 mM potassium phosphate pH 6.0; 1 mM NBD; 1 mM hydrogen peroxide; 12% (v/v) acetonitrile). Absorption values (λ: 425 nm) of each well were immediately measured after addition in a kinetic mode (measurement interval: 30 s) over a duration of 5 min. Slope values of absorption increase corresponding to 4-nitrocatechol formation were obtained, paying special attention to the linearity of the observed

slope to obtain reliable relative NBD conversion values for comparison of the respective wells.

Resting-state absorption and haem CO complex measurements. The pooled and dialysed elution fractions (100 mM potassium phosphate pH 7.0) were subsequently used to record absorption spectra of the respective enzymes (*Mro*UPO, *Cg*UPO, *Mth*UPO, *Tte*UPO) in their native, resting state (ferric iron; Fe³⁺). For all measurements, a QS High precision Quartz Cell cuvette (Hellma Analytics, Müllheim, DE) with a path length of 10 mm was used. Spectra were recorded on a Biospectrometer Basic device (Eppendorf, Hamburg, DE) in the spectral range from 250 to 600 nm (interval: 1 nm) and subtracting the utilised storage buffer (100 mM potassium phosphate pH 7.0) as previous blank measurement. Haem carbon dioxide spectra (CO assay) were recorded after reducing the haem iron to its ferrous form (Fe²⁺). Therefore, a spatula tip of sodium dithionite as the reducing agent was added to 1 mL of a respective enzyme fraction (see above) and mixed thoroughly till complete dissolution. This sample was immediately flushed with a constant carbon dioxide flow for 2 min (approx. 1 bubble/sec) to obtain the thiolate-haem carbon dioxide complex. The sample was immediately transferred to a cuvette and absorption measured as described above. The CO assay was also employed for the measurement of peroxxygenase concentrations in the concentrated *P. pastoris* supernatant obtained after ultrafiltration. In this case, the supernatant was 10-fold diluted with potassium phosphate buffer (100 mM, pH 7.0). A spatula tip of sodium dithionite was then added to 2 mL of the diluted supernatant sample. After dividing the respective sample into two parts of 1 mL, one part was treated with carbon monoxide for 2 min as described above, and the CO untreated sample is used as a blank reference. Absorption measurements were performed by UV/Vis spectroscopy using a JASCO V-770 Spectrophotometer (JASCO Deutschland GmbH, Pfungstadt). The CO absorption maximum was measured at 444 nm, and a reference absorption wavelength was measured at 490 nm. For calculation, an extinction coefficient of 91,000 M⁻¹ cm⁻¹ was used, which appears to be generally valid for most haem-thiolate enzymes according to literature⁶. The enzyme concentration in the supernatant was then calculated using the formula:

$$c[\mu\text{M}] = \text{dilution factor} \times \frac{A_{444\text{nm}} - A_{490\text{nm}}}{0.091\mu\text{M}^{-1}\text{cm}^{-1}}$$

pH range of NBD conversion. pH dependency of NBD conversion of the respective enzymes was investigated using different buffer system in the range between pH 2.0 and 11.0 (even numbers only). Each buffer was prepared as a 100 mM stock solution, potassium phosphate buffer was used for the pH values 2.0, 7.0 and 8.0. Sodium citrate was used in the range of pH 3.0 to 6.0 and Tris-HCl was used in the range of pH 8.0 to 11.0. Purified enzyme solutions (100 mM potassium phosphate pH 7.0) were diluted 10 to 20x fold in ddH₂O prior to the measurements leading to weakly buffered solutions as screening samples. The NBD assay was then performed as described before, mixing 20 μL of the enzyme dilution with 180 μL screening solution (87 mM corresponding buffer pH x; 500 μM NBD; 1 mM H₂O₂). All samples were measured as three biological replicates. Due to the strong pH-dependency of the molar extinction coefficient of the corresponding detected product 4-nitrocatechol a normalisation was performed. Therefore, the product 4-Nitrocatechol was prepared as 10 mM stock solution dissolved in acetonitrile and diluted into 990 μL of the corresponding screening buffer (final concentration: 10 μM) and after 5 min an absorption spectrum in the interval of 400 to 600 nm (Biospectrometer Basic device) recorded. Calculation of the correction factor of the respective samples (pH 2.0 to pH 11.0) was then performed regarding the utilised measurement wavelength of 425 nm. Finally, in consideration of the obtained pH correction factor, individual activity values derived from the respective measured absorption values were calculated.

Protein concentration determination and purification yield. Protein concentrations of the respective protein samples were determined after dialysis of the elution fractions (storage buffer: 100 mM potassium phosphate pH 7.0). In this regard, the colorimetric BCA assay was utilised, employing a Pierce™ BCA Protein Assay Kit (ThermoFisherScientific, Waltham, US) following the instructions of the manufacturer. Samples were measured in biological triplicates (25 μL of a previously diluted sample) and concentrations calculated based on a previously performed calibration curve using BSA (0–1000 μg/mL) as reference protein. To determine the overall yield of enzyme production per litre of culture volume, the determined concentration in the elution fraction was extrapolated to the overall NBD activity of the sample after ultrafiltration (column load). This calculation is performed since NBD is a highly specific substrate for peroxxygenase activity, comparable background samples processed in a similar manner but using empty plasmid controls did not show any measurable conversion of NBD. Samples of every purification step (load, flow-through, wash and elution fraction) were collected, and NBD conversion rates of the respective fractions measured immediately after purification. In the case of non-complete binding of the enzyme fraction (remaining NBD activity in flow-through fraction) this remaining non-bound enzyme amount was taken into consideration for calculation for the overall volumetric production yield. The via BCA assay determined protein concentration of the elution fraction was extrapolated to the activity of the respective non-bound fraction, assuming a constant specific enzyme activity for NBD conversion and

considering the volumes of the respective fractions, leading to an approximate enzyme titre per litre.

SDS gel analysis and PNGaseF treatment. Obtained elution fractions of the respective UPO enzymes were analysed for the apparent molecular weight and overall purity after the performed one step TwinStrep purification by means of SDS PAGE. Therefore, samples of the column load (after ultrafiltration; see above), elution fractions after dialysis and deglycosylated elution fraction samples were analysed on self-casted SDS PAGE (10 or 12% of acrylamide) utilising a Bio-Rad (Hercules, US) Mini-Protean® Gel electrophoresis system. A defined PageRuler Prestained Protein Ladder (ThermoFisherScientific, Waltham, US) was included, covering a MW range between 10 and 180 kDa. Proteins were visualised using a colloidal Coomassie G-250 staining solution. To obtain N-type deglycosylated protein samples, elution fractions were enzymatically treated with Peptide-N-Glycosidase F (PNGaseF) from *Flavobacterium meningosepticum*, which is capable of cleaving Asparagine linked high mannose type glycan structures as typically occurring in *P. pastoris* and *S. cerevisiae* derived glycosylation patterns. Therefore, 45 μL of a respective elution fraction was mixed with 5 μL of denaturing Buffer (final 0.5% SDS; 40 mM DTT) and denatured for 10 min (100 °C). After a cooling step to room temperature 6 μL of NP-40 solution (final: 1 %) and 6 μL of Glyco-Buffer2 (500 mM sodium phosphate; pH 7.5) were added and the solution thoroughly mixed. Finally, 1 μL of PNGaseF (New England Biolabs, Ipswich, US) was added and the sample incubated under light shaking (37 °C) for 3 h. After incubation, the sample was prepared for further analysis by adding 5x fold SDS sample buffer and subsequent SDS PAGE analysis executed as described before. In the case of native deglycosylation, 90 μL of enzyme sample were mixed with 10 μL of GlycoBuffer2 (500 mM Sodium Phosphate; pH 7.5) and 1 μL of PNGaseF added. The mixture was incubated at 37 °C in a thermal PCR cycler (24 or 48 h) and subsequently analysed for UPO activity in comparison with an equally treated sample (without PNGaseF addition) by means of the NBD assay (see above).

Protein identification by MS. Protein samples after protein purification (in 100 mM Tris-HCl pH 8.0, 150 mM NaCl; 50 mM biotin) were enzymatically digested with trypsin and desalted according to ref. 77. The resulting peptides were separated using C18 reverse-phase chemistry employing a pre-column (EASY column SC001, length 2 cm, ID 100 μm, particle size 5 μm) in line with an EASY column SC200 with a length of 10 cm, an inner diameter (ID) of 75 μm and a particle size of 3 μm on an EASY-nLC II (all from Thermo Fisher Scientific). Peptides were eluted into a Nanospray Flex ion source (Thermo Fisher Scientific) with a 60 min gradient increasing from 5% to 40% acetonitrile in ddH₂O with a flow rate of 300 nL/min and electrosprayed into an Orbitrap Velos Pro mass spectrometer (Thermo Fisher Scientific). The source voltage was set to 1.9 kV, the S Lens RF level to 50%. The delta multipole offset was -7.00. The AGC target value was set to 1e06 and the maximum injection time (max IT) to 500 ms in the Orbitrap. The parameters were set to 3e04 and 50 ms in the LTQ with an isolation width of 2 Da for precursor isolation and MS/MS scanning. Peptides were analysed using a Top 10 DDA scan strategy employing HCD fragmentation with stepped collision energies (normalised collision energy 40, 3 collision energy steps, width 15). MS/MS spectra were used to search the TAIR10 database (<ftp://ftp.arabidopsis.org>, 35394 sequences, 14486974 residues) amended with target protein sequences with the Mascot software v.2.5 linked to Proteome Discoverer v.2.1. The enzyme specificity was set to trypsin, and two missed cleavages were tolerated. Carbamidomethylation of cysteine was set as a fixed modification and oxidation of methionine. Searches were performed with enzyme specificity set to trypsin and semi-trypsin to identify truncated protein N-termini. The precursor tolerance was set to 7 ppm, and the product ion mass tolerance was set to 0.8 Da. A decoy database search was performed to determine the peptide spectral match (PSM) and peptide identification false discovery rates (FDR). PSM, peptide and protein identifications surpassing respective FDR thresholds of $q < 0.01$ were accepted.

UPO bioconversions for subsequent GC-MS and chiral HPLC analytics. For the tested hydroxylation (naphthalene, phenylethane, -propane, -butane and -pentane) and epoxidation (styrene) reactions, purified UPOs enzyme samples (stored in 100 mM potassium phosphate; pH 7.0) produced in *S. cerevisiae* were used. Respective reactions (total volume: 400 μL) were performed as biological triplicates in 100 mM potassium phosphate (pH 7.0) containing 100 nM of UPO, 1 mM of the respective substrate and 500 μM H₂O₂. The substrate was prior dissolved in pure acetone (20 mM stock solution) yielding a 5% (v/v) co-solvent ratio in the final reaction mixture. Reactions were performed for 60 min (25 °C, 850 rpm) and subsequently quenched by the addition of 400 μL ethyl acetate (internal standard: 1 mM ethyl benzoate). Extraction was accomplished by 30 s of vigorous vortexing, followed by brief centrifugation (1 min, 8400 rpm). The organic layer was then utilised for respective GC-MS measurements as described in Supplementary Table 7. In the case of the hydroxylation reaction of N-phthaloyl-phenylethyl amine, purified UPOs enzyme samples (stored in 100 mM potassium phosphate, pH 7.0.) previously produced in *P. pastoris* were used. Reactions (total volume: 500 μL) were performed as biological triplicates in 100 mM potassium phosphate (pH 7.0) containing 100 nM of the respective UPO, 250 μM of the substrate N-phthaloyl-phenylethyl amine and 250 μM H₂O₂. The substrate was prior dissolved in pure

acetone (5 mM stock solution) yielding a 5% (v/v) co-solvent ratio in the final reaction mixture. Reactions were performed for 60 min (30 °C, 850 rpm) and subsequently quenched by the addition of 650 μ L ethyl acetate (internal standard: 1 mM ethyl benzoate). Extraction was accomplished by 30 s of vigorous vortexing, followed by brief centrifugation (1 min, 8400 rpm). 200 μ L of the resulting organic layer were utilised for GC-MS measurements. The remaining organic solvent was evaporated using a mild nitrogen stream, the precipitate resolved in 200 μ L isopropanol and utilised for chiral HPLC measurements. For the larger scale hydroxylation reaction of *N*-phthaloyl-phenylethyl amine with *Cg*UPO general procedures were followed as described above with some slight alterations. In contrast to the previous small-scale reaction (500 μ L), within this approach, ten reactions (each total volume: 1 mL) were performed in parallel in 100 mM potassium phosphate (pH 7.0) containing 250 nM *Cg*UPO, 250 μ M substrate and 250 μ M H₂O₂. Reactions were performed for 60 min (30 °C, 850 rpm) and subsequently quenched by the addition of 1 mL ethyl acetate to each reaction. Extraction was accomplished by 30 s of vigorous vortexing, followed by brief centrifugation (1 min, 8400 rpm). The organic layers of all samples were combined, and the solvent was gradually evaporated using a mild nitrogen stream. The precipitate was then resolved in 200 μ L isopropanol and utilised for chiral HPLC measurements (Supplementary Figs. 18–20).

Achiral gas chromatography-mass spectrometry (GC-MS). Measurements were performed on a Shimadzu GCMS-QP2010 Ultra instrument (Shimadzu, Kyoto, JP) using a SH-Rxi-5Sil MS column (30 m x 0.25 mm, 0.25 μ m film, Shimadzu, Kyoto, JP) or OPTIMA 5MS Accent column (25 m x 0.20 mm, 0.20 μ m film, Macherey-Nagel, Düren, DE) and helium as carrier gas. 1 μ L of each sample was injected splitless with an injection temperature of 280 °C. The split/splitless unliner inlets (3.5 mm, 5.0 x 95 mm for Shimadzu GCs, deactivated wool) from Restek (Bad Homburg, DE) were utilised and regenerated if needed by CS-Chromatography (Langerwehe, DE). The temperature program was adjusted, as shown in Supplementary Table 7. The interface temperature was set to 290 °C. Ionisation was obtained by electron impact with a voltage of 70 V, and the temperature of the ion source was 250 °C. The MS is equipped with dual-stage turbomolecular pumps and a quadrupole enabling a selected ion monitoring acquisition mode (SIM mode). Calibration and quantification were implemented in SIM mode with the corresponding *m/z* traces, as shown in Supplementary Table 7. The detector voltage of the secondary electron multiplier was adjusted in relation to the tuning results with perfluorotributylamine. The GC-MS parameter was controlled with GCMS Real Time Analysis, and for data evaluation, GCMS Postrun Analysis (GCMSsolution Version 4.45, Shimadzu, Kyoto, JP) was used.

Chiral gas chromatography-mass spectrometry (GC-MS). Measurements were performed on a Shimadzu GCMS-QP2020 NX instrument (Shimadzu, Kyoto, JP) with a Lipodex E column (25 m x 0.25 mm, Macherey-Nagel, Düren, DE) and helium as carrier gas. 1 μ L of each sample was injected splitless with an OPTIC-4 (Shimadzu, Kyoto, JP) injector utilising a temperature profile in the liner (35 °C, 1 °C/s to 220 °C hold 115 s). The column temperature program was adjusted as shown in Supplementary Table 7. The interface temperature was set to 200 °C. Ionisation was obtained by electron impact with a voltage of 70 V, and the temperature of the ion source was 250 °C. The MS is equipped with dual stage turbomolecular pumps and a quadrupole enabling a selected ion monitoring acquisition mode (SIM mode). Calibration and quantification were implemented in SIM mode with the corresponding *m/z* traces, as shown in Supplementary Table 7. The detector voltage of the secondary electron multiplier was adjusted in relation to the tuning results with perfluorotributylamine. The GC-MS parameters were controlled with GCMS Real Time Analysis, and for data evaluation GCMS Postrun Analysis (GCMSsolution Version 4.45, Shimadzu, Kyoto, JP) was used.

GC-MS calibration curves. For product quantification, calibration curves were created as depicted in Supplementary Fig. 15. The quantification was achieved in Scan mode (*N*-(2-hydroxy-2-phenylethyl) phthalimide) or SIM mode (all other substrates) whereby each concentration data point was measured as triplicates and correlated to an internal standard (IS). The final product concentration was adjusted in 100 mM potassium phosphate buffer (pH 7.0) with the corresponding stock solutions in acetone yielding to 5% (v/v) final co-solvent proportion in the buffer system. Extraction was achieved adding 650 μ L (*N*-(2-hydroxy-2-phenylethyl)phthalimide) or 400 μ L (all other substrates) of ethyl acetate (containing 1 mM of the internal standard) and vortexing for 30 s, followed by brief centrifugation (1 min, 8400 rpm). The organic layer was utilised for GC-MS measurements applying the corresponding temperature program as listed in Supplementary Table 7. For enantiomeric product identification corresponding R-enantiomer standards were utilised (Supplementary Fig. 16).

Preparative work

***N*-Phthaloyl-phenylethyl amine.** Phthalic anhydride (0.59 g, 4.0 mmol), phenylethyl amine (0.51 mL, 4.0 mmol) were dissolved in dichloromethane (40 mL) at room temperature. Molecular sieves (4 Å pore diameter) and triethylamine (2.0 mL, 14.5 mmol) were added, and the reaction mixture was refluxed for 36 h. After the reaction was completed (TLC control) the mixture was filtered, and the solvent was

evaporated under reduced pressure. The residue was dissolved in ethyl acetate, washed with sodium bicarbonate solution and water and dried over sodium sulphate. After filtration, the product was obtained under reduced pressure to yield 0.31 g (80%) as an orange solid. No further purification was necessary.

¹H-NMR (400 MHz, CDCl₃): δ 7.83 (dd, *J* 5.4, 3.1 Hz, 2H), 7.70 (dd, *J* 5.5, 3.0 Hz, 2H), 7.32 – 7.17 (m, 5H), 3.96 – 3.90 (m, 2H), 3.02 – 2.95 (m, 2H) ppm;

¹³C-NMR (100 MHz, CDCl₃): δ 168.15, 137.99, 133.88, 132.06, 128.83, 128.53, 126.62, 123.19, 39.27, 34.60 ppm;

MS (ESI, MeOH): *m/z* 274.1 ([M + Na]⁺), calcd: 251.09.

(*R,S*)-2-*N*-Phthaloyl-1-phenylethanol. Phthalic anhydride (0.30 g, 2.0 mmol) and 2-amino-1-phenylethanol (0.27 g, 2.0 mmol) were placed into a microwave vessel under stirring (magnetic). The vessel was heated to 150 °C for 30 min in the microwave reactor. After cooling to room temperature, the product was washed with HCl (1 M, 20 mL) and recrystallised from dichloromethane/*n*-hexane to yield 0.47 g (89%) as colourless crystals.

¹H-NMR (400 MHz, CDCl₃): δ 7.82 (dd, *J* 5.4, 3.1 Hz, 2H), 7.70 (dd, *J* 5.5, 3.0 Hz, 2H), 7.48 – 7.40 (m, 2H), 7.39 – 7.27 (m, 3H), 5.06 (dt, *J* 8.6, 4.2 Hz, 1H), 4.07 – 3.85 (m, 2H), 3.03 (d, *J* 5.0 Hz, 1H) ppm;

¹³C-NMR (100 MHz, CDCl₃): δ 168.69, 141.02, 134.06, 131.81, 128.53, 128.03, 125.83, 123.39, 72.47, 45.67 ppm;

MS (ESI, MeOH): *m/z* 268.1 ([M + H]⁺), 290.0 ([M + Na]⁺), calcd: 267.09.

(*S*)-(+)-2-*N*-Phthaloyl-1-phenylethanol (chemical conversion). Phthalic anhydride (0.30 g, 2.0 mmol) and (*S*)-(+)-2-amino-1-phenylethanol (0.27 g, 2.0 mmol) were placed into a microwave vessel under stirring (magnetic). The vessel was heated to 150 °C for 30 min in the microwave reactor. After cooling to room temperature, the product was washed with HCl (1 M, 20 mL) and recrystallised from dichloromethane/*n*-hexane to yield 0.44 g (82%) as colourless crystals.

¹H-NMR (400 MHz, CDCl₃): δ 7.85 (dd, *J* 5.5, 3.1 Hz, 2H), 7.73 (dd, *J* 5.5, 3.1 Hz, 2H), 7.50 – 7.27 (m, 5H), 5.19 – 4.96 (m, 1H), 4.10 – 3.86 (m, 2H), 2.97 – 2.78 (m, 1H) ppm;

¹³C-NMR (100 MHz, CDCl₃): δ 168.75, 141.05, 134.13, 131.88, 128.60, 128.11, 125.86, 123.46, 72.68, 45.76 ppm;

MS (ESI, MeOH): *m/z* 289.9 ([M + Na]⁺), calcd: 267.09;

$$[a]_{20}^D + 23.9(c0.75, \text{CHCl}_3).$$

(*S*)-(+)-2-*N*-Phthaloyl-1-phenylethanol (enzymatic conversion). *N*-Phthaloyl-phenylethyl amine (15.8 mg, 62.9 μ mol) was dissolved in acetone (15 mL) and poured into a solution of potassium phosphate buffer (100 mM, 263 mL, pH 7.0), hydrogen peroxide (210 μ M, 3.2 mL) and *Mth*UPO (250 nM, 15 mL). The solution (total: 300 mL) was stirred at 30 °C for 1 h. Afterwards the mixture was extracted using ethyl acetate (3 x 60 mL). The organic phase was washed with brine, dried with sodium sulphate, filtered and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel using dichloromethane/ethyl acetate with 1% formic acid (1/5 \rightarrow 1/1) obtaining 9.70 mg (57 %) (*S*)-(+)-2-*N*-Phthaloyl-1-phenylethanol as a pale-yellow solid.

¹H-NMR (400 MHz, CDCl₃): δ 7.86 (dd, *J* 5.5, 3.1 Hz, 2H), 7.73 (dd, *J* 5.5, 3.0 Hz, 2H), 7.49 – 7.43 (m, 2H), 7.42 – 7.27 (m, 3H), 5.08 (dd, *J* 8.7, 3.6 Hz, 1H), 4.11 – 3.86 (m, 2H), 2.83 (s, 1H) ppm;

¹³C-NMR (100 MHz, CDCl₃): δ 168.76, 141.04, 134.14, 131.89, 128.62, 128.13, 125.86, 123.48, 72.72, 45.77 ppm;

MS (ESI, MeOH): *m/z* 289.9 ([M + Na]⁺), calcd: 267.09;

$$[a]_{20}^D + 21.0(c1.55, \text{CHCl}_3).$$

***N*-Phthaloyl-2-oxo-phenylethyl amine.** (*R,S*)-*N*-Phthaloyl-phenylethanol (0.18 g, 0.67 mmol) was dissolved in dimethyl sulfoxide (6 mL) at room temperature. Under ice cooling, acetic anhydride (1.2 mL) was added, and the reaction mixture was stirred for 16 h at room temperature. After the reaction was completed (TLC control) the mixture was quenched with ethyl acetate (20 mL), and the mixture was washed with sodium perchlorate solution (6 %), sodium thiosulfate solution (10 %) and brine and dried over sodium sulfate. After filtration, the product was obtained under reduced pressure to yield 0.15 g (84 %) as a colourless solid. No further purification was necessary.

¹H-NMR (400 MHz, CDCl₃): δ 8.06 – 7.98 (m, 2H), 7.91 (dd, *J* = 5.5, 3.0 Hz, 2H), 7.76 (dd, *J* = 5.5, 3.0 Hz, 2H), 7.69 – 7.48 (m, 3H), 5.14 (s, 2H) ppm;

¹³C-NMR (100 MHz, CDCl₃): δ 190.94, 167.88, 134.43, 134.11, 134.02, 132.25, 128.89, 128.14, 123.55, 44.19 ppm;

MS (ESI, MeOH): *m/z* 288.1 ([M + Na]⁺), calcd: 265.07.

Column and analytic thin layer chromatography. All solvents for column chromatography were purchased from Merck Millipore (Darmstadt, DE) and distilled prior to use. Column chromatography was carried out using Merck silica gel 60 (40–63 μ m). For analytic thin layer chromatography, Merck TLC silica gel 60 F254 aluminium sheets were used. Compounds were visualised by using UV light (254/366 nm).

Nuclear magnetic resonance (NMR). NMR spectra were recorded using a 400 MHz Agilent DD2 400 NMR spectrometer at 25 °C. The chemical shifts of ¹H NMR spectra are referenced on the signal of the internal standard tetramethylsilane ($\delta = 0.000$ ppm). Chemical shifts of ¹³C NMR spectra are referenced on the solvent residual signals of CDCl₃ ($\delta = 77.000$ ppm).

Electrospray ionisation mass spectrometry (ESI-MS). ESI mass spectra were recorded on an API3200 Triple Quadrupole mass spectrometer (AB Sciex) equipped with an electrospray ion source (positive spray voltage 5.5 kV, negative spray voltage 4.5 kV, source heater temperature 400 °C).

Specific optical rotation. Specific optical rotations of compounds were recorded on a P-2000 Digital Polarimeter (JASCO, Pfungstadt, DE) utilising a wavelength of 589 nm.

Chiral HPLC. HPLC chromatograms were recorded on an Agilent High Performance LC (Agilent Technologies, Waldbronn, DE). The used chiral column material was Chiralpak AS-H HPLC (Daicel, Tokyo, JP) (25 cm × 4.6 mm). Substances were dissolved in HPLC-grade isopropanol prior to analysis, and a sample volume of 5 μ L injected. The eluent (20% isopropanol, 80% *n*-hexane) was used in a flow rate of 1 mL/min with the runtime of 30 min at 30 °C.

Microwave reactions. Microwave reactions were carried out using an Initiator + device (Biotage, Düsseldorf, DE).

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

The authors declare that the data supporting the findings of this study are available within the paper and its Supplementary Information files. Source data is provided as Supplementary Data 1.

The focus of this chapter has been the implementation of a versatile GC-MS analysis technique amendable for the identification of improved enzyme variants embedded in complex biological matrices within high throughput screening setups. The established methodology coined MISER (**m**ultiple **i**njections in a **s**ingle **e**xperimental **r**un) could be successfully implemented within two diverse enzyme screening setups, utilising whole cell *E. coli* biocatalysts and peroxygenase containing cultivation supernatant of *Saccharomyces cerevisiae*. Aiming to expand the current diversity of recombinant UPOs, we constructed a DNA shuffling library originating from three long-type UPO genes and comprising up of 243 unique combinations. Six novel UPO chimeras were identified as active catalysts through the MISER screening approach.

Identification of Novel Unspecific Peroxygenase Chimeras and Unusual YfeX Axial Heme Ligand by a Versatile High-Throughput GC-MS Approach

Catalyst discovery and development requires the screening of large reaction sets necessitating analytic methods with the potential for high-throughput screening. These techniques often suffer from substrate dependency or the requirement of expert knowledge. Chromatographic techniques (GC/LC) can overcome these limitations but are generally hampered by long analysis time or the need for special equipment. The herein developed multiple injections in a single experimental run (MISER) GC-MS technique allows a

substrate independent 96-well microtiter plate analysis within 60 min. This method can be applied to any laboratory equipped with a standard GC-MS. With this concept novel, unspecific peroxygenase (UPO) chimeras, could be identified, consisting of subdomains from three different fungal UPO genes. The GC-technique was additionally applied to evaluate an YfeX library in an *E. coli* whole-cell system for the carbene-transfer reaction on indole, which revealed the thus far unknown axial heme ligand tryptophan.

Introduction

In the last decades, highly successful and environmentally benign catalytic methodologies have been developed in organic chemistry. The discovery and development of these catalysts have been primarily based on rational or intuitive approaches and serendipitous findings.^[1] Improving the outcome of unexpected findings necessitates high-throughput experimentation that enables the analysis of several thousand reactions. Several smart strategies were developed like DNA templating,^[2] sandwich immunoassay,^[3] MALDI labelling,^[4] fluorescence quenching and UV absorption.^[5] These techniques have their distinct advantages but typically rely on expert knowledge, specialized laboratories or labelled substrates. For protein engineering,

most setups rely on colorimetric or fluorescence based assays amongst them also microfluidic-based ultra-high throughput systems.^[6] The ideal assay would i) allow the screening with the exact substrate of interest, ii) be highly sensitive, iii) be exceedingly reproducible and iv) require minimal time-periods for analysis. To be applicable in standard chemical and biochemical laboratories, the necessary instrumentation should be sufficiently general and accessible. A flexible and sensitive analytical technique is provided by chromatographies such as liquid (LC) or gas chromatography (GC). While these techniques often provide the necessary sensitivity and are applicable to a wide range of substrates, they suffer from long analysis times preventing a high-throughput screening with several hundreds of samples a day. The time consuming parts are the separation, washing/heating and column equilibration. Higher throughput was enabled by method, column and gradient optimisation yielding total run times of less than four minutes.^[7]

Intriguing developments have brought substantially shortened analysis times for LC by ultrahigh performance liquid chromatography (UHPLC) and GC by flow field thermal gradient gas chromatography (FF-TG-GC).^[8] However, these techniques are not available in every laboratory (UHPLC), only a few prototypes are existing (FF-TG-GC), or a higher throughput cannot be achieved with conventional approaches (GC/LC). The analysis of multiple, overlapping samples in one chromatogram, coined multiplexing, has been introduced in 1967 by Izawa for GC^[9] and was extended by Trapp and co-workers for a high-throughput approach. This technique requires a specifically built injector system. A method to enhance throughput in standard LC measurements is the multiple injections in a single experimental run (MISER) approach.^[10] This method does not require special equipment or expert knowledge.

MISER relies on the injection of several samples under isocratic conditions into one chromatographical run requiring baseline separation of the peaks. This enabled the performance of long chromatographic separations in a high-throughput manner as usually signal and therefore information free areas in the chromatogram are filled by peaks of multiple injections.^[10–11] The method of MISER-GC-MS has not yet been employed for large sample numbers,^[12] but seems highly suitable for the application in a high-throughput screening based on several reasons:

- MISER allows a distinct throughput enhancement for GC without requiring special equipment,
- the quantification of target substances by GC-MS extracted from crude mixtures is far less prone to ion suppression by matrix effects than by LC-MS systems and,^[13]
- MS-based detection is highly sensitive and allows quantification of low analyte concentrations in complex mixtures.

Herein, we report the development of a novel MISER-GC-MS strategy paving the way for a versatile, assay-independent platform for catalytic reactions. The developed system is applicable for any GC-MS equipped with an autosampler. Thereby, the MISER-GC-MS technique was broadened to measure several analytes combined with an internal standard to compensate deviations and enables the quantification of multiple molecules with overlapping peak areas eliminating the need for chromatographical separation. To facilitate the data evaluation, an R-script has been written, allowing rapid analysis and quality control. The developed technique enabled the screening of two libraries with different host organisms and reactions (Figure 1).

Results and Discussion

Development of a versatile MISER-GC-MS approach for highly reproducible 96-well analysis in biological matrices

A standard autosampler was modified for fast injection application by decoupling of the autosampler from the GC instrument (Supporting Information). The read-out-signal of the GC was suppressed, enabling an independent control of the autosampler. The method development commenced by altering various conditions at the autosampler. The setup optimisations like post-cleaning with isopropanol after each injection, as well as variations in filling speed and the number of filling strokes, were performed using the analyte ethyl 3-indoleacetate. This led to significantly decreased standard deviations from initially 51.6 to 6.5% (Table S2) illustrating the importance of adjusting the settings of the autosampler for multiple injections set up.

Since the MS-detection allows the simultaneous quantification of different m/z signals, the system was expanded to an internal standard (methyl indole-3-carboxylate). The correlation between the analyte and an internal standard enabled the error minimisation occurring due to solvent evaporation, extraction and sample injection and allows the comparability of microtiter plates. For MISER-GC-MS method verification, three different ethyl 3-indoleacetate concentrations (20, 50 and 90 μM) were employed with a constant concentration of internal standard. All MISER runs ought to be isocratic. The lowest oven temperature of 150 °C led to peak tailing and poor baseline separation (Figure 2A, left). Utilising a temperature of 190 °C resulted in an excellent baseline separation and improved peak shapes as well as a reduced standard deviation of 4.0% using 20 μM ethyl 3-indoleacetate (Table S3).

Further parameters, which were investigated, were the split ratio, the MS mode (SIM or Scan) and the injection interval (Figure 2, Figure S6). To avoid overlapping of the injection and analyte peaks, the injection interval was altered from 67 s to 82 s. This further lowered the standard deviation and allowed the increase of the split ratio up to 60, resulting in excellent standard deviations of 1.0% for 20 μM ethyl 3-indoleacetate. With these optimised analytical conditions in hand, we further challenged the system by using *E. coli* cell lysates spiked with ethyl 3-indoleacetate and analysed the resulting samples in 96-well experiments using methyl indole-3-carboxylate as an internal standard. As further quality control and for calibration purposes ethyl 3-indoleacetate (20 μM) extracted from a buffer system was injected after each microtiter plate row (12 samples) as well as standards at the end of the run. The system was assessed with the best conditions of the GC system (190 °C, split ratio 60, and 82 s injection interval) leading to a standard deviation of 4.0% for 109 injections including controls (Figure 2B, left). This could be even further improved to a standard deviation of 2.5% by increasing the oven temperature to 230 °C. Due to shorter retention times on the

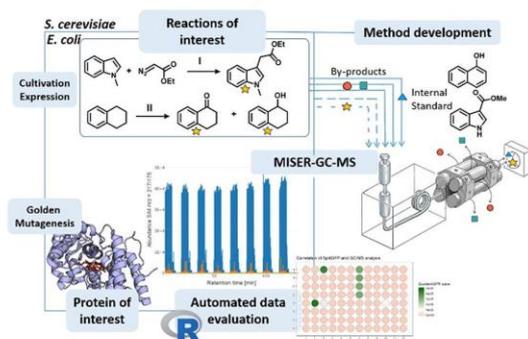

Figure 1. MISER-GC-MS and its implementation for the identification of novel enzymatic activities enabled the investigation of two case studies in different biological matrices: I) carbene-transfer reaction on 1-methyl indole (*E. coli*) and II) hydroxylation of 1,2,3,4-tetrahydronaphthalene (*S. cerevisiae*).

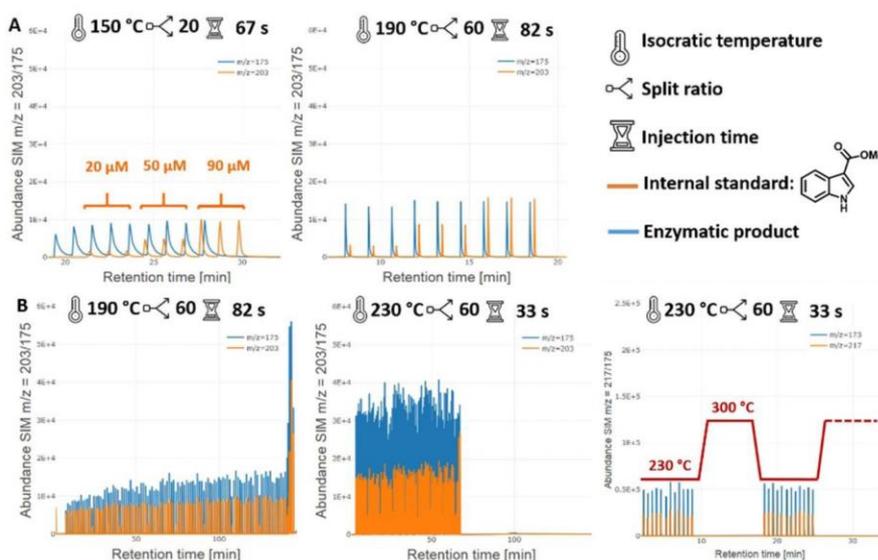

Figure 2. A) Method development with the analytes ethyl 3-indoleacetate (m/z 203) and methyl indole-3-carboxylate (m/z 175) with three different concentrations of ethyl 3-indoleacetate (20, 50 and 90 μM). B) Transferring the best conditions into 96-well format using a biological matrix (*E. coli* lysate). An alternative stacked method, including intermediate heating cycles, was developed with 3-(*N*-methyl-indole)acetate (m/z 217).

column, this also allowed a quicker injection interval of 33 s (Figure 2B, middle, Table S6).

Since the developed methods shall be applicable for the screening of non-natural enzyme activities, which in general suffer from low turnovers and require high substrate loading, the contamination of the GC column could pose a substantial problem within 96 injections. Heating intervals can remove such contaminations.^[12b] An additional method was therefore developed, which includes a heating cycle after every 12th sample (Figure 2B, right). With a split ratio of 60 a standard deviation of 3.0% was reached. These different techniques and setups were applied to the screening of enzyme libraries (see below). Since the assessment of hundreds of samples results in large amounts of data points, an automated R-script was written to ensure high quality and correct peak integration in each microtiter plate (see Additional Material). The script assesses the data of the MISERgram for reproducibility using the internal standard. Based on the injection interval, the peaks are counted to verify whether every sample has been correctly injected (GC hardware) and integrated (GC software). The quotient of the internal standard and product peak is illustrated as a bar chart and colour-coded microtiter plate for fast data evaluation.

The new MISER-GC-MS system was now applied to two different enzyme systems to screen protein libraries in altering biological systems.

Screening of a focussed enzyme library of the YfeX-catalysed carbene-transfer reaction revealed tryptophan as a novel axial heme ligand

The dye-decolourising peroxidase YfeX from *E. coli* was previously shown to perform non-natural carbene-transfer reactions^[14] such as carbonyl olefination^[15] and C–H functionalisation.^[16] The starting activity for the latter reaction was previously improved by an alanine scan within the active site.^[16]

We were subsequently interested in the influence of the axial ligand on the activity of YfeX regarding the C–H functionalisation reaction. The axial ligand complexes the heme iron and substantially influences its redox potential and electrophilicity and hence the overall activity of the occurring heme-carbenoid complex.^[17] The starting point of the mutagenesis was a variant carrying the mutations D143V, S234C and F248V (parental variant). To study the influence of the axial ligand in YfeX, we performed saturation mutagenesis targeting the axial ligand residue histidine 215 – using the recently developed Golden Mutagenesis protocol and its online tool^[18] – and screened the resulting library for the occurrence of other functional axial ligands in whole-cell reactions by using the interval heating method for MISER-GC-MS. To ensure the quality of the generated library, a quick quality control (QQC) was conducted, demonstrating the expected codon distribution (Figure S11). The reaction was performed using the carbene-transfer reaction on 1-methyl-indole with ethyl diazoacetate as carbene donor (Supporting Information).

As a control, cells harbouring the empty plasmid (pAGM22082) and the parental YfeX were included within the 96 well plate, which could be clearly distinguished by MISER-GC-MS (Figure 3). To our delight, a new variant was identified, which carried a highly unusual tryptophan residue as axial heme ligand. To prove that the MISERgram revealed a "true positive" result, the corresponding plasmid was freshly transformed, expressed, and the corresponding protein purified by metal affinity chromatography. These results confirmed the YfeX-H215W variant, showing only slightly reduced activities compared to the parental variant (Figure S12). This discovery could broaden the spectrum of canonical amino acids as axial ligands for non-natural reactions^[17c,19] as well as represent an interesting target structure for the further development of non-canonical amino acids for heme complexing.^[17b,20]

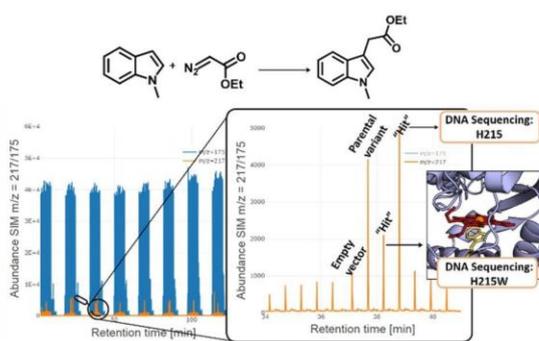

Figure 3. 96-well analysis of the carbene-transfer reaction by the previously developed stacked method for MISER-GC-MS. As controls, the empty vector was included in column 6 and the parental YfeX variant in column 7, which harbours the axial ligand H215.

Screening of a fungal unspecific peroxygenase (UPO) chimera library in *S. cerevisiae* with the substrate tetralin revealing six novel peroxygenase constructs

To demonstrate that the MISER-GC-MS method can be readily applied to other reactions and environments, the screening was applied to fungal unspecific peroxygenases^[21] (UPOs) for its hydroxylation of tetralin. The previous method development demonstrated that simultaneous quantification of product and an internal standard is possible. We here wanted to expand the analysis to three different molecules: tetrahydronaphthol (main reaction product), α -tetralone (side-product) and 1-naphthol (internal standard). Method development was based on the results, as stated above. The two products and the internal standard were injected in three different concentrations, and the MS response was compared to the obtained values when injecting only one analyte at a time and all three simultaneously. The results revealed minimal deviation comparing single and multiple m/z trace analysis (Figure 4A, Figure S4). To confirm the accuracy of the refined MISER-GC-MS method, we selected one possible functional variant (chimera I, Figure 4B), which was previously identified by a standard colorimetric assay (unpublished results). The aim was to validate a MISER-GC-MS technology enabling the analysis of an entire microtiter plate with individually expressed variants with an overall standard deviation of less than 10%. We were delighted to see that the measurement of the entire 96 well plate within an analysis time of 60 minutes showed a standard deviation of only 9.7% for the formation of tetrahydronaphthol (Figure 4B).

UPOs represent a class of highly promising enzymes, which show remarkable activities as well as stabilities and solely consume hydrogen peroxide as co-substrate. A major bottleneck, however, is the heterologous enzyme expression. Even though several thousands of putative peroxygenases have been assigned, only very few could be produced heterologously thus far.^[21b,22] To create structural diversity

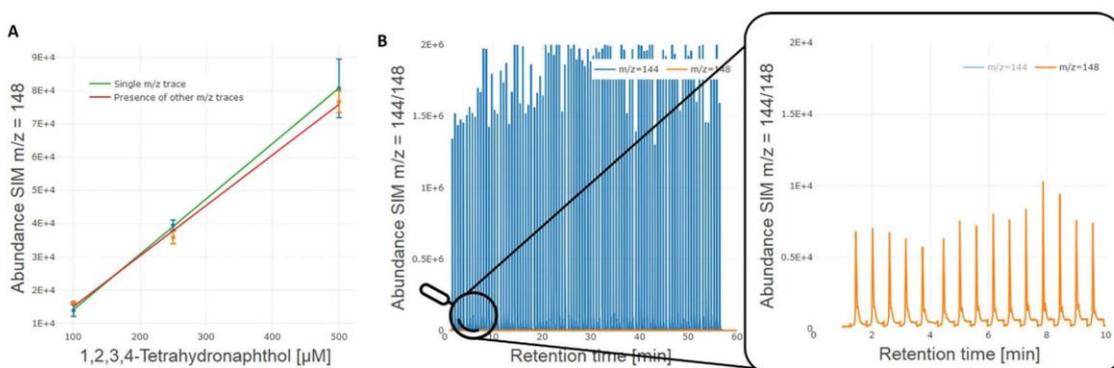

Figure 4. A) Extraction and mass spectrometric analysis of 1,2,3,4-tetrahydronaphthol in presence and absence of the other two compounds within a MISER experiment, B) MISERgram of the hydroxylation of 1,2,3,4-tetrahydronaphthalene with 96 biological replicates in microtiter plate format with a standard deviation of 9.7%.

three (putative) UPO genes from different fungal origins bearing high sequence similarity were selected for the construction of a shuffled peroxygenase library: the yeast secretion variant PaDa-I originating from *Agrocybe aegerita*, *GmaUPO* from *Galerina marginata* (72% identity) and *CciUPO* from *Coprinopsis cinerea* (62% identity).^[21b,22] The wildtype enzymes *GmaUPO* and *CciUPO* showed no activity and no expression in *S. cerevisiae*, respectively. The secondary structural units were grouped, and sequence subunits were created by loop cuts yielding five subunits for each

gene (Figure 5). The structural assignment was done based on the crystal structure of PaDa-I (pdb: 5OXU).^[23]

The secondary structure consists of 13 helices (42% of overall sequence) and 15 beta sheets (6%). The units were then grouped based on not disrupting pivotal catalytic motives (PCP; EGD; E196) and secondary structure elements such as alpha helices and beta sheets (see Figure S15 for details). These subunits were randomly shuffled, leading to $3^5 = 243$ possible combinations. Cultivation, as well as biotransformation, were implemented in a high-throughput manner using 96 well microtiter plates. Besides the analytics of the product formation, the peroxygenases were equipped with a C-terminal split-GFP-tag thus allowing the determination of the protein concentration.^[24] The screening of 672 transformants by MISER-GC-MS was done in seven hours and revealed 34 hits. Figure 6 depicts a resulting MISERgram of one microtiter plate. The best performing variants from this library were reproduced in four individual biological replicates in a microtiter plate, confirming the accuracy of this method (Figure S14).

From the previously identified chimeras I-V (unpublished results), only the chimera I, II, III and V showed activity towards tetralin and could be identified during the MISER-GC-MS screening. However, a novel construct Chimera VI could be identified, and the parental variant PaDa-I was rediscovered three times. Based on the GFP signal, the chimera VI showed a 3.8 fold enhanced secretion compared to PaDa-I (Supporting Figure S14B) and demonstrated a good starting point for a heterologously expressed UPO, which can be screened on additional substrates.

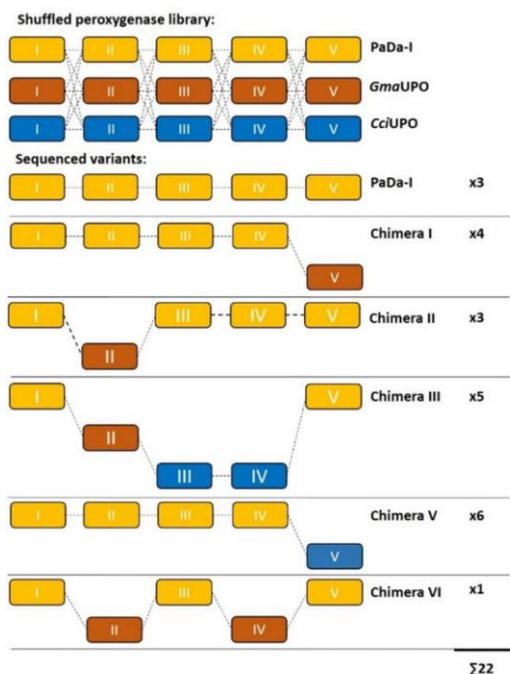

Figure 5. Subunits of the shuffled peroxygenase library and repetitive identified hits which were analysed by MISER-GC-MS and subsequently sequenced.

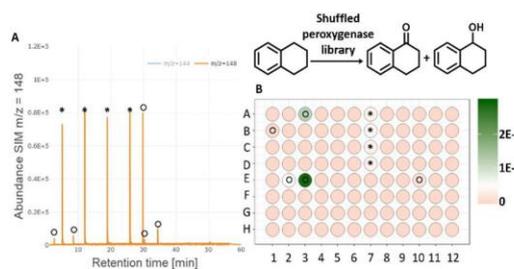

Figure 6. Screening of a fungal unspecific peroxygenase library. A) MISERgram of microtiter plate 1, B) automated R-script evaluation of plate 1 (O = identified hit, * = PaDa-I as control).

Conclusions

The development of MISER-GC-MS methods was successfully utilised for its identification of novel enzyme activities. Two methods were developed: one method for the screening of natural enzymatic reactions, which generally have only a few side-products and therefore an injection interval of 33 s was applied for 96 well microtiter plate analysis within 60 min. The other developed technique was the stacked method with particular relevance to low activities and large amounts of side-products, including a heating step after every 12th injection to improve the quality of the acquired data.

Both systems were employed for the screening of two different enzyme classes and reactivities within two biological systems. For the YfeX catalysed carbene-transfer reaction, the screening of a focused library led to a highly unusual axial heme ligand (H215W). By screening a chimera library of three shuffled unspecific peroxygenase genes, MISER-GC-MS aided the detection of five peroxygenase chimeras. These chimeras were active and heterologous producible catalysts and hence provide access to new peroxygenase scaffolds.

To put the MISER-GC-MS in perspective to the colorimetric assay based on 4-nitrocatechol formation: the 96-well

analysis of the colorimetric product 4-nitrocatechol takes 2 minutes. It has a sensitivity in the range of 10–20 μM , which amounts to 2000–4000 pmol (200 μL volume in one micro-titer plate well). MISER-GC-MS revealed an analysis time of 60 minutes with a detection limit of 5–10 μM corresponding to 0.08–0.17 pmol (1 μL sample injection and a split ratio of 1:60). The high sensitivity of MISER-GC-MS could enable the engineering of minute initial activities for new unnatural reactions in the future.

The herein demonstrated MISER-GC-MS technology can be implemented into any laboratory with a GC-MS equipped with an autosampler and has proven potential as a versatile, specific and cost-effective high-throughput approach.

Experimental Section

Biological procedures

Lysate preparation for extraction experiments. The YfeX WT gene (cloned into pAGM22082) was transformed into chemically competent *E. coli* BL21 (DE3) pLysS cells (Merck Millipore, Darmstadt, DE) by heat shock. Freshly-plated transformants were grown overnight in 5 mL TB medium containing kanamycin and chloramphenicol (50 $\mu\text{g}/\text{mL}$ each). 2 mL of the pre-culture was then used to inoculate 400 mL of main culture consisting of TB autoinduction medium containing kanamycin and chloramphenicol (50 $\mu\text{g}/\text{mL}$ each). Cells were incubated at 37 °C and 120 rpm. After 4 h of initial cultivation, aqueous solutions of $\text{FeCl}_3/5$ -aminolevulinic acid (final concentration: 100 μM) were added, the temperature was reduced to 30 °C, and the cells were incubated for further 16.5 h. Cells were harvested by centrifugation (3000 $\times g$, 20 min, 4 °C). The supernatant was discarded, and the pellet was resuspended in binding buffer (50 mM KPi, pH 7.0, 200 mM NaCl). Cells were lysed by sonication (Bandelin Sonoplus HD3100: 6 \times 30 s, 70% amplitude, pulse mode). The resulting lysate was stored at –20 °C until further utilisation for lysate extraction experiments.

Site-saturation mutagenesis (SSM) and *E. coli* cultivation in 96-deep-well plates. Mutagenesis was performed using the Golden Mutagenesis technique^[18] combined with the “22c-trick”^[25] for randomisation. The YfeX gene from *E. coli* was chosen as a template, targeting amino acid residue position Histidine 215. The created library was then transformed into chemically competent *E. coli* BL21 (DE3) pLysS cells. A pre-culture of the transformants was grown in 350 μL TB medium with added kanamycin and chloramphenicol (50 $\mu\text{g}/\text{mL}$ each) in an EnzyScreen plate at 37 °C and 300 rpm overnight. For the main culture, 730 μL of TB autoinduction medium per well (plus 50 $\mu\text{g}/\text{mL}$ kanamycin and chloramphenicol and 100 μM of $\text{FeCl}_3/5$ -aminolevulinic acid) was inoculated with 20 μL of the respective pre-culture. In a first phase the cells were cultivated at 37 °C and 300 rpm for 4 h. Afterwards the temperature was decreased to 25 °C and protein expression was continued overnight. The cells were harvested by centrifugation (30 min, 3000 g, 4 °C) and the supernatant discarded.

Whole-cell biotransformation with YfeX. The 96 deep well plate harbouring the cell pellets was transferred into a glove box (N_2 atmosphere) and incubated on ice for 1 h to remove residual oxygen from the gas phase. 200 μL of degassed 50 mM KPi buffer (pH 7.0, 200 mM NaCl, 2 mM MgCl_2) was added to each well, and the cells were resuspended by vortexing for 1 min. 200 μL of a reaction master mix (stock solutions: 50 mM

1-methylindole, 50 mM ethyl diazoacetate, 100 mM sodium dithionite) were added to each well (final concentration: 2.5 mM 1-methylindole, 2.5 mM ethyl diazoacetate, 10 mM sodium dithionite and 20% ethanol as co-solvent) and the plate was closed tightly with a cover. The reaction was performed at 30 °C and 300 rpm for 1 h. The samples were extracted by addition of 1 mL ethyl acetate (EtOAc) containing 100 μM methyl indole-3-carboxylate as internal standard and shaking at 300 rpm for 20 min at 25 °C. After centrifugation (10 min, 3000 g, 10 °C) 400 μL of the organic phase were transferred into a glass-coated 96-well plate for GC-MS analysis.

Expression and purification of YfeX variants for hit verification. The YfeX gene and its corresponding mutants (plasmid backbone: pAGM22082) were transformed into chemically competent *E. coli* BL21(DE3) pLysS cells by heat shock procedure. Freshly-plated transformants were grown overnight (160 rpm) as pre-culture in 5 mL TB medium containing chloramphenicol and kanamycin (50 $\mu\text{g}/\text{mL}$ each). 2 mL of the pre-cultures were used to respectively inoculate 400 mL TB auto-induction medium (+ kanamycin and chloramphenicol). Cells were incubated at 37 °C (120 rpm shaking). After 4 hours of cultivation, aqueous solutions of FeCl_3 and 5-aminolevulinic acid (final concentration: 100 μM) were added and the temperature reduced to 30 °C. The cells were incubated for further 16.5 h. Cells were finally harvested by centrifugation (3000 $\times g$, 20 min, 4 °C). The cultivation supernatant was discarded, and the pellets were resuspended in binding buffer (50 mM KPi; pH = 7.4, 200 mM NaCl, 1 mg/ml lysozyme, 100 $\mu\text{g}/\text{mL}$ DNase I). Cells were lysed by sonication (Bandelin Sonoplus HD3100: 6 \times 30 s, 70% amplitude, pulse mode). The cell debris was removed by centrifugation for 45 min at 4 °C and 6000 $\times g$. The proteins exhibiting an N-terminal attached hexahistidine-Tag were purified by IMAC (immobilised metal ion affinity chromatography) using 1 mL His GraviTrap TALON columns (GE Healthcare Europe GmbH, Freiburg, DE). After applying the cleared supernatant to the column, the column was washed with 10 column volumes (10 mL) of washing buffer (50 mM KPi; pH = 7.4, 200 mM NaCl, 5 mM imidazole). YfeX variants were finally eluted by the addition of elution buffer (50 mM KPi; pH = 7.4, 200 mM NaCl and 250 mM imidazole). For subsequent buffer exchange of the pooled elution fractions PD-10 desalting columns (GE Healthcare Europe GmbH, Freiburg, DE) were used according to the manufacturer's protocol. YfeX samples were eluted using 50 mM KPi (pH = 7.0) with addition of 10% glycerol (v/v) as storage buffer. Afterwards samples were flash frozen in liquid nitrogen and stored at –20 °C. Protein concentrations were determined in duplicates using the Pierce TM BCA Protein Assay Kit (Thermo Scientific, Rockford, US).

Purified enzyme biotransformation. For the purified enzyme biotransformation the whole cell biotransformation conditions were adapted and the final enzyme concentration was set to 15 μM . The reaction was performed at 30 °C and 600 rpm for 1 h. The samples were extracted by addition of 1 mL EtOAc containing 100 μM methyl indole-3-carboxylate as internal standard and vortexing. After centrifugation (5 min, 20.000 g) 600 μL of the organic phase were transferred into glass vials for subsequent GC-MS analysis.

Amino acid sequence of the YfeX parental variant. Plasmid derived N-terminal hexahistidine-tag + T7 tag indicated in *italic*. The C-terminal GFP11 detection tag is underlined. Mutations in comparison to the YfeX wild type protein sequence (Uniprot ID: P76536) are indicated as bold letters.

Yeast supernatant preparation for extraction experiments. The empty plasmid (lacking UPO gene) for yeast expression was transformed into chemically competent yeast cells (INVSc1 strain) by polyethylene glycol/lithium acetate transformation. For the preculture 100 ml SC Drop selection Media (lacking Uracil as supplement; containing 2% raffinose as carbon source and 25 µg/ml chloramphenicol) were inoculated with a single yeast colony from a previously grown SC Drop out plate (lacking Uracil) at 30 °C and 130 rpm for 2 days. For expression rich expression media (Yeast extract Peptone Galactose) containing 2% of galactose as inducer was utilised. The final main culture OD was adjusted by addition of the preculture to 0.3. Expression was performed for further 72 h (120 rpm; 30 °C). After 72 h cultivation time cells were separated from the supernatant by centrifugation (3400 rpm; 45 min; 4 °C). The supernatant was stored at 4 °C until further utilisation for supernatant extraction experiments.

Generation of a shuffled peroxygenase gene library and Yeast cultivation in 96-well plates. The gene of the peroxygenase yeast secretion mutant PaDa-1,^[21b] an annotated peroxygenase gene from the fungus *Galerina marginata* and previously described peroxygenase from *Coprinopsis cinerea*^[22] were divided into 5 structural subunits and randomly shuffled together (243 possible combinations). Full length fragments were then reassembled into a yeast expression plasmid (Galactose inducible promoter) with an N-terminal signal peptide and a C-terminal GFP 11 detection tag within a single Golden Gate cloning reaction (unpublished results). Corresponding plasmid mixtures were transformed into yeast cells (INVSc1 strain) by polyethylene glycol/lithium acetate transformation. Yeast cells were cultivated in liquid culture as described by Molina Espeja *et al.*^[21b] with slight modifications. 220 µl of minimal expression medium per well (containing 2% (w/v) Galactose final concentration as carbon source and inducer) were inoculated with a single yeast colony from a previously grown SC Drop out plate (lacking Uracil). For cultivation EnzyScreen half-deepwell plates were utilised. Expression was performed for 72 h (230 rpm; 30 °C). After 72 h cultivation time cells were separated from the peroxygenase containing supernatant by centrifugation (3400 rpm; 45 min; 4 °C). For subsequent screening 20 µL (for split GFP Assay) and 100 µL (for biotransformation) were transferred to a respective plate using a multichannel pipet.

Supernatant biotransformation in *S. cerevisiae* for peroxygenases. A volume of 100 µL of the peroxygenase containing yeast supernatant was transferred to a 96-well EnzyScreen plate (CR1496), followed by the addition of 240 µl of 100 mM citrate buffer (pH 6), 40 µl of 1,2,3,4-tetrahydronaphthalene stock solution (10 mM in acetonitrile, final concentration: 1 mM) and 20 µl H₂O₂ stock solution (6 mM in H₂O, final concentration: 300 µM). After a centrifugation step (1 min, 100×g, 10 °C), the reaction was shaken for 16 h at 230 rpm and 30 °C. The reaction was stopped by addition of 400 µl freshly prepared 500 µM internal standard extraction solution (1-naphthol in EtOAc). For extraction the aqueous and organic solution were shaken for additional 20 min at 300 rpm. After centrifugation (3000×g, 5 min, 10 °C), 300 µl of the organic layer was transferred to a glass coated plate for GC analysis.

Split-GFP assay. Protein normalisation was performed employing the principle of a split GFP normalisation assay as described by Santos-Aberturas *et al.*^[24b] with slight modifications. The complementation fragment sfGFP 1–10 was cloned into the Golden Mutagenesis plasmid pAGM22082_cRed² for T7 promoter controlled expression in *E. coli*. For measurement 20 µl of yeast expression supernatant was transferred to a previously BSA blocked 96 well Nunc MaxiSorp Fluorescence plate (ThermoFisherScientific, Waltham, US) and 180 µl of sfGFP 1–10 inclusion body preparation added. Immediate fluorescence values (GFP fluorophore: excitation wavelength: 485 nm; emission wavelength: 535 nm; top read mode) was measured using a 96 well plate fluorescence reader (TECAN, Grödig, AT). After storage over two nights (at 4 °C) final fluorescence values were measured. Protein quantities were then normalised based on the relative fluorescence increase (differential values) and in comparison to the empty plasmid backbone.

Based on the previous identification of novel wild type UPOs, within this chapter a directed evolution campaign towards increased conversion of NBD has been conducted. Therefore *MthUPO*, originating from the thermophilic fungus *Myceliophthora thermophila*, has been chosen as target for evolution by utilising *S. cerevisiae* as heterologous UPO production host. Nine amino acid positions within the active site and substrate access channel were chosen and subsequently randomised through single and double-site saturation mutagenesis and recombination of beneficial mutations, leading to a total of 5300 produced and screened primary transformants. The triple variant L60F/S159G/A161I exhibited a 16.5-fold increase in catalytic efficiency ($k_{\text{cat}}/K_{\text{M}}$) for NBD conversion when compared to the wild type enzyme. Harnessing the panel of evolved active *MthUPO* variants, further screenings of naphthalene and substituted derivatives led to substantial shifts in product formations. For the conversion of 2-methylnaphthalene three differing chemoselectivities depending on the respective enzyme variant could be assessed.

Accessing Chemo- and Regioselective Benzylic and Aromatic Oxidations by Protein Engineering of an Unspecific Peroxygenase

KEYWORDS: Chemoselectivity, Unspecific Peroxygenase, Protein Engineering, Naphthoquinone, Biocatalysis.

ABSTRACT: Unspecific peroxygenases (UPOs) enable oxyfunctionalisations of a broad substrate range with unparalleled activities. Tailoring these enzymes for chemo- and regioselective transformations represents a grand challenge due to the difficulties in their heterologous productions. Herein, we performed protein engineering in *Saccharomyces cerevisiae* using the

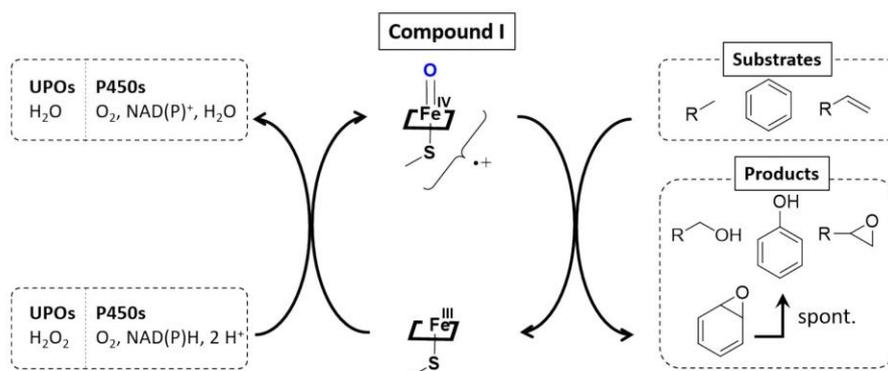

novel *Mth*UPO from *Myceliophthora thermophila*. More than 5,300 transformants were screened. This protein engineering led to a significant reshaping of the active site as elucidated by molecular dynamics. The reshaping was responsible for the increased oxyfunctionalisation activity, with improved k_{cat}/K_m values of up to 16.5-fold for the model substrate 5-nitro-1,3-benzodioxole (NBD). Moreover, variants were identified with high chemo- and regioselectivities in the oxyfunctionalisation of aromatic and benzylic carbons, respectively. The benzylic hydroxylation was demonstrated to perform with excellent enantioselectivities of up to 95 % *ee*. The proposed evolutionary protocol and rationalisation of the enhanced activities and selectivities acquired by *Mth*UPO variants, represent a step forward towards the use and implementation of UPOs in biocatalytic synthetic pathways of industrial interest.

INTRODUCTION

Fungal unspecific peroxygenases (UPOs) are haem-containing proteins that catalyse oxyfunctionalisation reactions of a broad substrate scope via an oxoferryl active species known as Compound I (Cpd I), analogous to hemeperoxidases and P450 monooxygenases (P450s).¹⁻⁴ UPOs utilise hydrogen peroxide as “pre-reduced” oxygen source and do not require additional reducing agents or reductase domains like P450s, which require NAD(P)H equivalents and electron transfer steps to activate molecular oxygen (Scheme 1).⁵⁻⁷ This facile Cpd I generation and its high activities renders UPOs very promising biocatalysts. UPOs have demonstrated in the last two decades to be highly efficient biocatalysts for carbon, sulfur and nitrogen oxyfunctionalisations.⁸⁻¹¹ They can activate C–H bonds of sp^3 -hybridised carbons enabling a homolytic cleavage.

Scheme 1. The formation of the catalytically active oxoferryl species (Cpd I) in P450s and UPOs and the oxyfunctionalisation of sp^2 - and sp^3 -hybridised carbons.

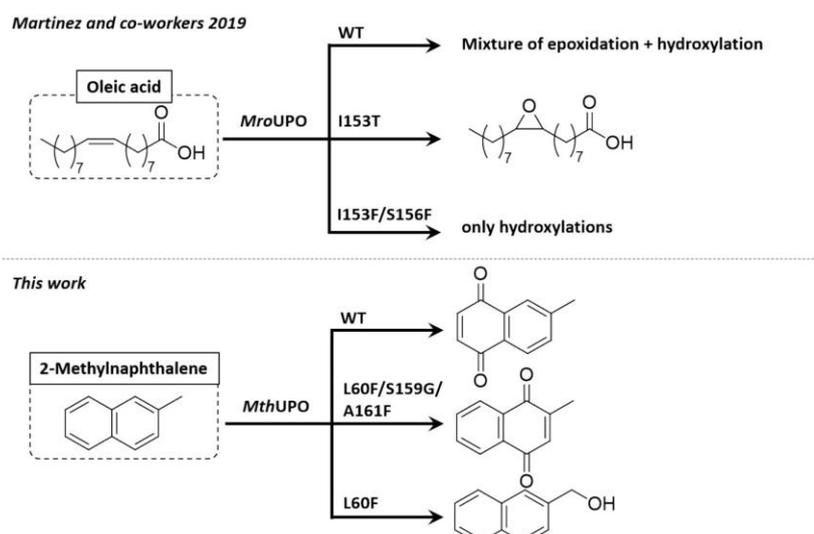

The resulting carbon radical rapidly reacts with the iron-bound OH-group in a second step to form the hydroxylation product and recover the resting state Fe(III) centre (Scheme 1). The

functionalisation of C–C double-bonds results in an epoxide formation, while for aromatic oxidations the initial epoxidation follows a spontaneous rearomatisation resulting in a formal hydroxylation product. Aromatic oxidations could also lead to the respective quinones, like naphthoquinone from naphthalene, which is assumed to proceed via the 1-naphthol formation followed by a peroxidase-type single electron oxidation.^{12, 13}

While the activity and stereoselectivity of UPO-catalysed reactions are auspicious for future synthetic and industrial applications, low regio- and chemoselectivities mostly afford product mixtures hampering their direct utilisation.

Scheme 2. Protein engineering of UPOs for chemoselective oxyfunctionalisations.

Examples for poor regioselectivities by most UPOs are the hydroxylations of saturated fatty acids,¹⁴ alkanes,^{15, 16} steroids¹⁷ and vitamin D3.¹⁸

Low chemoselectivities are observed for unsaturated fatty acids,¹⁴ and a range of linear and cyclic alkenes.^{19, 20} Although advances have been made by engineering new P450 variants,^{21, 22} there is a need to develop more selective UPOs to overcome these limitations.

The shortcomings of UPOs are mostly addressed by smart substrate selections. Whereas, for example, toluene leads to a mixture of *ortho*, *para* and benzylic hydroxylations with *Aae*UPO from *Agroclybe aegerita* (syn. *Cyclocybe aegerita*), utilising phenylethane resulted in the specific hydroxylation of the benzylic carbon.^{19, 23} This change in the selectivity trend was likely due to the higher reactivity of the secondary C(sp³)-H of the benzylic phenylethane (estimated bond dissociation energy (BDE) 83.0 kcal/mol compared to the respective primary C-H bond in toluene (BDE 86.7 kcal/mol, Figure S17)).

To increase the applicability of UPOs as useful biocatalysts, accessing substrate-independent and selective hydroxylations are of utmost importance. This selectivity increase could be achieved by protein engineering. Protein engineering encompasses the random or rational variation of enzyme amino acid sequences to alter their properties like activity, substrate scope, selectivity or stability and tolerance to different reaction conditions. In most cases, altering the protein for desired activities requires the assessment of large enzyme libraries.^{2, 22, 24, 25} The development of a high throughput compatible, heterologous UPO expression system in *Saccharomyces cerevisiae* enabled protein engineering of UPOs.^{26, 27} With this advancement, various impressive directed evolution endeavours were pursued aiming towards improved UPO expression,²⁷ neutral drift²⁸ and efficient hydroxypropranolol formation.^{29, 30}

Recently, a first approach addressing the chemoselectivity issues of UPOs has been reported.³¹ An *E. coli* expression system was developed, which, although thus far not high throughput capable, allowed first studies on a few point mutations of *Mro*UPO from *Marasmius rotula*. Using

molecular dynamics (MD) simulations to explore substrate-binding pathways, haem channel modifications were predicted to influence the epoxidation and hydroxylation, respectively, on the unsaturated fatty acid oleic acid. While the wildtype showed hydroxylated and epoxidised products, variant I153T had a strongly enriched epoxide formation. The double mutant I153F/S156F, on the other hand, completely abolished the epoxide formation and exclusively showed hydroxylation regioisomers (Scheme 2).

We have recently established the heterologous expression of a set of UPOs in *S. cerevisiae* and *Pichia pastoris*.³² The therein discovered *Mth*UPO from the thermophilic fungus *Myceliophthora thermophila* demonstrated the thus far highest shake flask expression yields, allowing a facile microtiter plate-based analysis. Contrary to the well-established *Aae*UPO, *Mth*UPO showed an altered substrate specificity. *Aae*UPO exhibited mostly single hydroxylation of naphthalene to naphthol³³ and the same applies for the secretion variant *Aae*UPO*.^{12,32} *Aae*UPO* also revealed the overoxidation to 1,4-naphthoquinone in small amounts caused by a sequential reaction after the 1-naphthol formation. However, different product ratios are observed for *Mth*UPO. This enzyme catalysed the naphthalene oxyfunctionalisation yielding 1-naphthol and 1,4-naphthoquinone almost in a 1:1 ratio.³² For benzylic hydroxylations, *Aae*UPO demonstrated the highest product yields for phenylethane and –propane, but strongly abolished and diminished benzylic product formations for phenylbutane and –pentane, respectively. *Mth*UPO showed the opposite tendency: the highest activities were observed for phenylbutane and –pentane and the lowest for phenylethane. Due to the ability of the *Mth*UPO to perform aromatic as well as benzylic hydroxylations efficiently, we hypothesised that by protein engineering, variants could be designed possessing distinct active site geometries enabling the control of the chemoselectivities towards either of the competing transformations. We were interested in 2-methylnaphthalene as a

target structure as naphthalene is readily oxidised by *Mth*UPO and therefore provides a good starting point, and also has an additional methyl group that offers a position for benzylic hydroxylation. Moreover, the oxidation product 2-methyl-1,4-naphthoquinone is vitamin K3 and hence of industrial interest.³⁴ To enable a colourimetric high-throughput screening, the 5-nitro-1,3-benzodioxole (NBD) assay³⁵ was selected as it utilises a substrate that bears an aromatic ring system, an sp³-carbon and has a comparable size as naphthalene. A naphthalene-based colourimetric assay would have been based solely on the chemically more facile aromatic hydroxylation and is hence less suitable to identify variants for benzylic and aromatic hydroxylations.

In the present work, a pre-screening of single and double saturation libraries was employed to identify relevant positions for activity and selectivity in the active site and the entrance channel of *Mth*UPO. The best performing variants were selected and combined in a large recombination library. In total, more than 5,300 transformants were assessed, which led to the discovery of variants with improved activities. Computational modelling based on extensive MD simulations suggested essential changes in the active site due to mutations that directly impacted on preferential substrate binding poses. When naphthalene and its derivatives were tested with the newly engineered variants, different chemoselective oxidation patterns at the benzylic and aromatic positions, respectively, were found. MD simulations described that different catalytically relevant binding poses are explored in each variant by 2-methylnaphthalene, indane, and related tested substrates, which are equivalent to those characterised for the NBD model substrate. The control achieved on the accessible binding poses for the substrates and their specific positioning towards the catalytic Cpd I active species is proposed to be responsible for controlling the chemo- and stereoselectivity observed in these aromatic and benzylic oxidations.

RESULTS AND DISCUSSION

Based on a homology model for *MthUPO*, a total of nine positions (L56, F59, L60, L86, F154, T155, S159, A161 and L206) were saturated (Figure 1) using the Golden Mutagenesis technique with the web tool for primer design.³⁶ The mutant library was transformed in *S. cerevisiae* producing the corresponding variants. We screened the library using the colourimetric NBD assay^{35, 37} in combination with the recently established split-GFP analysis in yeast.^{38, 39} The split-GFP^{40, 41}

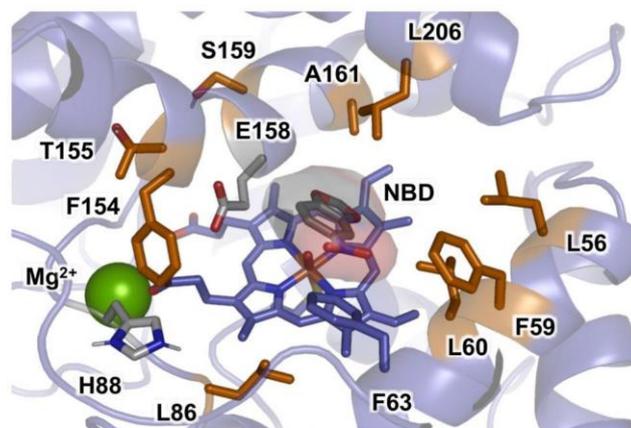

Figure 1. Active site arrangement of *MthUPO* with the NBD substrate bound obtained from MD simulations based on the generated homology model. Important active site residues, catalytic residues and NBD substrate are shown in sticks. The nine positions initially randomised are highlighted in orange, catalytic residues (H88, E158) and NBD substrate are shown in gray, important active site residue (F63) is shown in purple and structural Mg^{2+} ion as green sphere.

system allows the direct quantification of protein concentrations. It consists of a 16 amino acid split-GFP tag, which is *C*-terminally attached to the protein of interest. By adding a truncated GFP, it recombines with the split-GFP tag and its resulting fluorescence restoration allows the quantification of the split-GFP carrying protein.

The combination of the NBD and the split-GFP assay enabled the distinction between substrate conversion and protein secretion. Variations at position L56 substantially influenced the expression of the enzyme. Only 52 % of the analysed transformants displayed a fluorescence response (Table S4). Site saturation at position L60 yielded improved variants with superior

TONs for the NBD conversion. The variants L60M (1.2-fold improvement relative to the wildtype), L60Q (1.3-fold) and L60F (2.7-fold) showed the most noticeable improvements (Table 1 and S5). The variant library of position F154, which is located at the entrance channel, turned out to be a pivotal position for the NBD conversion.

Table 1. The catalytic activity of *MthUPO* variants for the hydroxylation of NBD.^a

<i>MthUPO</i> variant	Conversion [%]	TOF [min ⁻¹]	TON
WT	29	72	4340
L60F	77	194	11610
L60F/S159G/A161F	84	210	12590
F59Q/L60M/S159G/F154A	77	192	11540
F59Q/L60F/S159G ^b	76	379	22760

^aTOF = turnover frequency, TON = turnover number, standard deviation < 3.2 %, Reaction conditions: 20 nM *MthUPO* variant, 300 μM NBD, 1 mM H₂O₂, 100 mM KPi buffer (pH 7), 5 % acetone (v/v), measurement conditions: absorbance was measured at 425 nm for one hour in triplicates, values were calculated with the corrected extinction coefficient of 10870 M⁻¹ cm⁻¹ (see Figure S2), ^b10 nM *MthUPO*.

Even though 81 % of the variants were secreted according to the split-GFP signal, only the rediscovered wildtype enzymes displayed activity (Figure S1, Table S4).

As the second step, we grouped two amino acid residues and saturated them simultaneously with a reduced codon degeneracy (NDT), thereby obtaining the double mutants L60F/F154I and L60F/F154V with a 1.2-fold improvement compared to the wildtype (Table S5).

The initial screening of the single and double saturation library provided us with the necessary insights for important residues. Residues, which had a positive or neutral influence on the NBD conversion, were selected for recombination. These positions and amino acids were F59Q, L60F/Q/M, A57I, F154I/V, S159N/G and A161I/F. Inspired by Reetz' single-, double-, and

triple-code saturation mutagenesis approaches,^{42,43} we chose to recombine all residues and variations in all combinatorial possibilities including the respective wildtype amino acid.

Table 2. Biochemical characterisation of the *Mth*UPO wildtype and the evolved variants towards the substrate NBD.^a

This combination led to 864 unique variants and required the screening of more than 2,300 transformants.

The recombination library resulted in the discovery of triple and quadruple mutations with up to 16.5-fold improved catalytic efficiencies (k_{cat}/K_m , Table 2). All of the most active variants harboured amino acid exchanges at the L60 position (L60F/M) and the mutation S159G. The kinetic measurements revealed 8.2-fold (F59Q/L60F/S159G), 10.8-fold (F59Q/L60M/S159G/F154A) and 16.5-fold (L60F/S159G/A161F) increased k_{cat}/K_m values relative to the wildtype (Table 2). Whereas the K_m value of NBD was decreased or similar to the wildtype, the values were significantly increased for H_2O_2 (Table S6). The k_{cat} for NBD, however, was substantially improved for the identified triple and quadruple mutants with an 18.6-fold increase for the variant L60F/S159G/A161F relative to the wildtype.

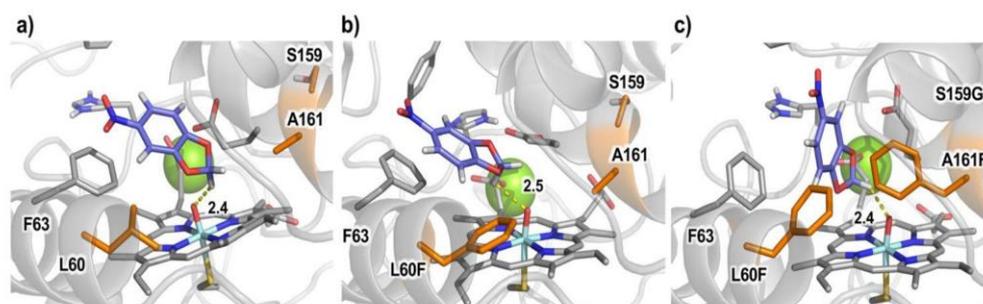

Figure 2. Active site arrangement of *MthUPO* and evolution of NBD's catalytically relevant binding modes in **a)** wildtype and the variants **b)** L60F and **c)** L60F/S159G/A161F as observed from MD simulations. Substrate, haem cofactor and important active site and catalytic residues are shown in sticks. The three mutated positions are highlighted in orange, NBD substrate is shown in purple, and structural Mg^{2+} ion as green sphere.

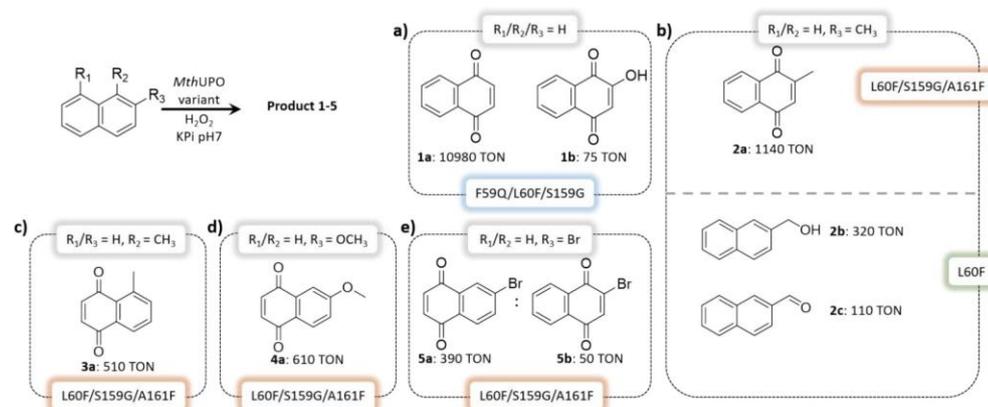

At this stage, we were interested in gaining some understanding of the changes induced by the mutations. Starting from the homology model for the *MthUPO* structure based on the solved crystal structure of the *MroUPO* (PDB: 5FUJ, 35 % identity), we refined it by

extensive molecular dynamics (MD) simulations accumulating a total of 5 μ s (5,000 ns) of simulation time (see Material and Methods for details). We then performed docking calculations that were used to obtain starting points for MD simulations in order to analyse the binding of NBD in the wildtype and the selected variants L60F and L60F/S159G/A161F (Figures 2, S9 and S10). These simulations revealed a switch in the binding mode of NBD when moving from wildtype to L60F and L60F/S159G/A161F. Due to the inclusion of bulkier, aromatic residues in the inner active site—first L60F, then A161F—the NBD substrate was reoriented from its original more buried binding pose in the wildtype to partially occupying the entrance channel in L60F/S159G/A161F. This new binding pose allows the NBD to better approach the oxyferryl Cpd I species in a near attack conformation for C–H abstraction, thus facilitating the oxidation reaction.

With these new engineered variants possessing different active site cavities, we were intrigued to probe their influence on the regio- and chemoselectivity on naphthalene derivatives (Scheme 3). The most active variants characterised from the NBD colourimetric assay were selected, and an initial screening on a substrate panel based on naphthalene and its derivatives was performed by GC-MS, resulting in significant changes in the oxidation patterns (Figure S4-S6).

Utilising a syringe pump setup achieved more than 10,000 TONs with variant F59Q/L60F/S159G for the conversion of naphthalene to 1,4-naphthoquinone **1a** (Scheme 3a). By increasing H₂O₂ equivalents, 2-hydroxy-1,4-naphthoquinone **1b** was formed as a by-product, which is a natural dye known as Lawsone.⁴⁴ Naphthalene conversion by the yeast expression variant of *AaeUPO* was previously shown to result in the predominant formation of 1- and 2-naphthol and 1,4-naphthoquinone only as a minor byproduct.¹²

Scheme 3. Catalytic activity of *Mth*UPO variants for the hydroxylation of naphthalene and its derivatives.^a

^areaction conditions were: 1 mM substrate, 4/5 mM H₂O₂ (end concentration), 50-500 nM *Mth*UPO variant, 100 mM KPi buffer pH 7, 5 % (v/v) acetone. Addition of 100-200 μL of an 8-16 mM H₂O₂ stock solution via a syringe pump within 1-2 h and additional stirring for 30 min to overnight. Details are shown in Table S7. Standard deviation of triplicates < 5.2 %.

The biotransformation of 2-methylnaphthalene with the wildtype led predominantly to 6-methyl-1,4-naphthoquinone (Figure S7). Variant L60F/S159G/A161F was able to shift the major product formation to 2-methyl-1,4-naphthoquinone (**2a**), also known as vitamin K₃, demonstrating the regioselectivity of this variant (Scheme 3b). We were pleased that we also identify the L60F variant with the preference for the methyl hydroxylation of 2-methylnaphthalene. This variant showed altered chemoselectivity dramatically suppressing the aromatic hydroxylation of the naphthalene core while accessing the hydroxylation of the methyl group (**2b**) as the major product. Also the overoxidation to the aldehyde was observed (**2c**, Scheme 3b).

To understand the switch in chemoselectivity when moving from L60F to L60F/S159G/A161F variants, we performed docking and MD simulations with 2-methylnaphthalene bound in both enzymes. MD simulations demonstrated that when 2-methylnaphthalene is bound in the L60F variant, only the methyl group was able to approach the active Fe=O species in a catalytically competent pose due to the presence of the bulky phenylalanine residue L60F (Figures 3 and S11). On the other hand, when 2-methylnaphthalene was bound into variant L60F/S159G/A161F, a binding pose similar to the previously observed NBD positioning in this variant was observed (Figures 3 and S12). This change in substrate positioning is promoted by hydrophobic interactions occurring in the newly engineered active site, which is dominated by the presence of several aromatic residues (F59, F60, F63, and F161). Within this new binding pose, the substituted aromatic ring of 2-methylnaphthalene is placed close enough to the oxyferryl (Cpd I) catalytic species to react while keeping the methyl group away from it. The different binding modes preferentially explored by 2-methylnaphthalene in these two variants are responsible for the observed switch in chemoselectivity (Figures S12 and S13).

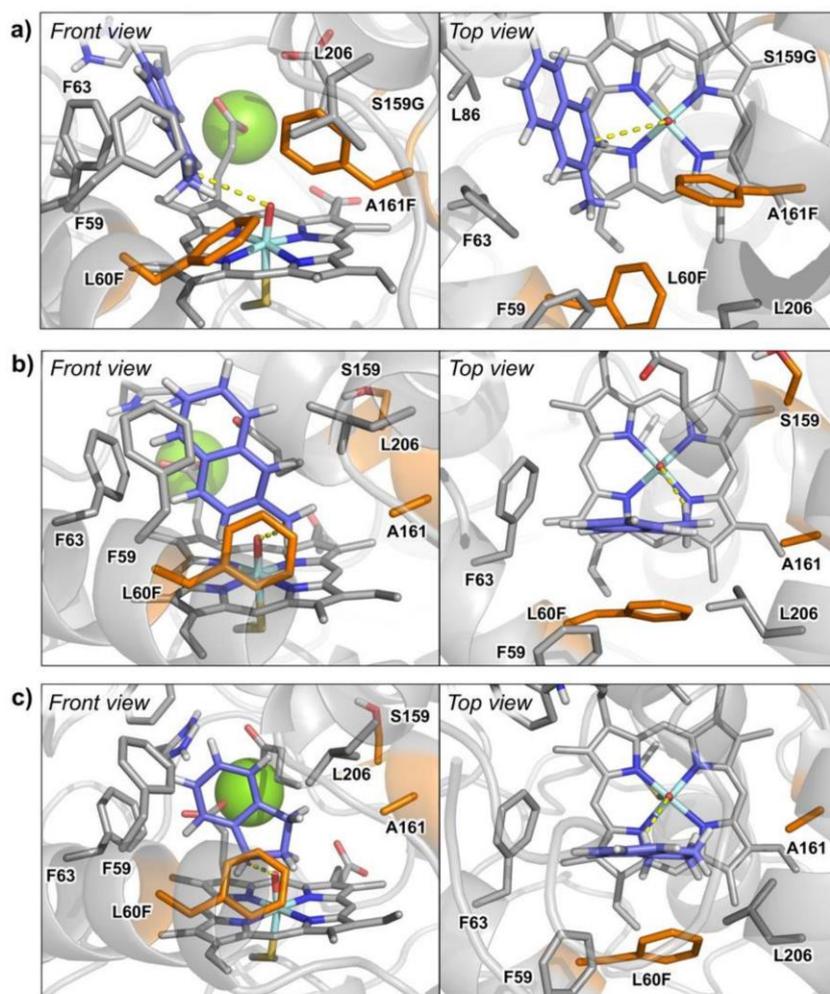

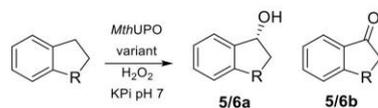

Figure 3. Catalytically relevant binding modes as characterised from MD simulations of **a)** 2-methylnaphthalene in L60F/S159G/A161F variant; **b)** 2-methylnaphthalene in L60F variant; and **c)** indane in L60F variant. Substrates, haem cofactor and important active site and catalytic residues are shown in sticks. The three mutated positions are highlighted in orange, substrates are shown in purple, and structural Mg^{2+} ion in green sphere.

Table 3. The catalytic activity of *Mth*UPO variants towards benzylic hydroxylation yielding chiral products.^a

R	<i>Mth</i> UPO variant	Product	TON	% <i>ee</i> ^[d]
CH ₂	L60F ^[a]	 5a	8160	95 (<i>R</i>)
CH ₂	L60F ^[a]	 5b	450	-
(CH ₂) ₂	L60F ^[b]	 6a	860	74 (<i>R</i>)
(CH ₂) ₂	F59Q/L60M/ S159G/F154A ^[c]	 6b	440	-

^aTON = turnover number, standard deviation < 6.5 %, reaction conditions: 100 nM *Mth*UPO variant, 1 mM indane, 1 mM H₂O₂, 100 mM KPi buffer (pH 7), 5 % acetone (v/v), 1 h at 25 °C in triplicates, ^b100 nM *Mth*UPO variant, 1 mM 1,2,3,4-tetrahydronaphthalene, 1 mM H₂O₂, 100 mM KPi buffer (pH 7), 5 % acetone (v/v), 1 h at 25 °C in triplicates, ^c100 nM *Mth*UPO variant, 1 mM 1,2,3,4-tetrahydronaphthalene, 2 mM H₂O₂, 100 mM KPi buffer (pH 7), 5 % acetone (v/v), 2 h at 25 °C in triplicates, [d] determined by chiral GC.

When 1-methylnaphthalene was considered, a decrease in the TONs of 50 % was observed yielding to the oxidation of the unsubstituted ring (Scheme 3c), as opposite to 2-methylnaphthalene. More surprisingly, also substitutions at 2 position of the naphthalene core led to the oxidation of the unsubstituted ring generating the 6-methoxy- (**4a**, Scheme 3d) and 6-bromo-1,4-naphthoquinone (**5a**, Scheme 3e) products with diminished TONs relative to 2-methylnaphthalene. For 2-bromo-naphthalene also 2-bromo-1,4-naphthoquinone (**5b**) was detected as a by-product.

To rationalise the different oxidation patterns observed for 1- and 2- substituted naphthalene derivatives, MD simulations were carried out. Simulations with variant L60F/S159G/A161F and 2-methoxy-naphthalene (Figures S13 and S14) revealed a preferential binding of the substrate in a region of the active site equivalent to the one observed for 2-methylnaphthalene. However, due to the presence of the bulkier methoxy group at the 2-position and the presence of the L60F residue, the naphthalene core in 2-methoxy-naphthalene needs to rotate slightly when approaching the Fe=O active species in a catalytically competent pose. This rotation places the 2-methoxy group away from the L60F and the haem cofactor and brings the unsubstituted aromatic ring closer to the Fe=O active species. Due to this proximity, a switch in the regioselectivity as compared to 2-methylnaphthalene occurred. Similar behaviour was also observed for 1-methylnaphthalene when bound in variant L60F/S159G/A161F in a catalytically competent pose (Figure S15).

Intrigued by the chemoselective benzylic hydroxylation catalysed by L60F, we tested this variant for the benzylic oxidation of indane and tetralin (1,2,3,4-tetrahydronaphthalene) investigating additional stereoselective control. L60F was able to convert indane with more than 8,000 TONs and improved enantioselectivity for the (*R*)-1-indanol (**5a**) from 85 % *ee* (wildtype)

to 95 % *ee* (Table 3 and S8). Interestingly, the examination of the variants L60F/S159G/A161F and F59Q/L60M/S159G/F154A revealed the loss of enantioselectivity and the excess in the formation of the (*S*)-enantiomer (Table S8). MD simulations with indane bound in variant L60F characterised a preferential binding pose of indane that resembles the previously observed pose for 2-methylnaphthalene in L60F (Figure 3 and S16). Simulations showed that indane mainly interacts with the aromatic rings of F63 and L60F, establishing C–H $\cdots\pi$ interactions. These hydrophobic interactions keep the substrate in a preferred binding pose where only the pro-*R* C(1)-H of the indane is close enough and well-aligned to the oxyferryl species to be efficiently hydroxylated.

For the bioconversion of tetralin to the alcohol **6a**, a substantially improved enantioselectivity for the (*R*)-enantiomer was detected for variant L60F (74 % *ee*) relative to the wildtype (45 % *ee*, Figure S8). Similar to indane, a variant could be identified, which forms the (*S*)-enantiomer (F59Q/L60M/S159G/F154A) predominantly.

CONCLUSIONS

The most important landmarks of UPOs are their discovery,⁸ the development of smart hydrogen peroxide delivery systems^{2, 19, 45} that allow their implementation in biocatalytic processes using milder reaction conditions, and their heterologous expression making them easily accessible.^{26, 27, 31, 32} The next step towards the broader applicability of UPOs as useful biocatalysts is to access more chemo-, regio- and stereoselective engineered UPO variants.

In this work, the recently characterised *Mth*UPO was engineered using a protein evolution protocol that involves site saturation mutagenesis and an extensive recombination library, making use of a split-GFP and colourimetric assays and a high-throughput yeast expression system that allowed us to screen more than 5,300 transformants. This led to *Mth*UPO variants that achieve

regioselective aromatic oxidations as well as chemoselective benzylic hydroxylations with 2-methylnaphthalene and other naphthalene derivatives.

Extensive MD simulations indicated that the origin of selectivity in these engineered *Mth*UPO variants is a reshaping of the active site cavity that controls which specific binding modes are accessible for the tested aromatic substrates.

The newly engineered variant L60F/S159G/A161F binds 2-methylnaphthalene in a catalytically relevant conformation that allows almost exclusively oxidation at the substituted ring. This binding mode yields the overoxidised 2-methyl-1,4-naphthoquinone (vitamin K₃) product. Vitamin K₃ (menadione) and the vitamin K family comprises 2-methyl-1,4-naphthoquinone derivatives, and the engineered selectivity provides a one-step direct route to access these molecules.

On the other hand, variant L60F possesses an active site that does not allow the aromatic moiety of 2-methylnaphthalene to productively approach to the reactive oxyferryl species, preferentially binding the substrate in a position where only the benzylic position can react. This resulted in a highly chemoselective benzylic hydroxylation and partly overoxidation to the aldehyde. Variant L60F also exhibit improved enantioselective benzylic hydroxylation of indane, which is shown to preferentially bind in L60F in a catalytically competed pose similar to 2-methylnaphthalene.

The presented work demonstrates the protein engineering towards chemo-, regio- and enantioselective oxyfunctionalisations catalysed by fungal unspecific peroxygenases, paving the way towards the broader application of UPOs in enzyme cascades, organic chemistry and industry.

MATERIALS AND METHODS

Chemicals. Solvents were used as provided without further purification from Carl Roth (Karlsruhe, DE) as GC ultra-grade. The commercially available compounds were also used without further purification from the following suppliers: *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA, Macherey-Nagel, Düren, DE), hydrogen peroxide solution (30 % (*w/w*) in H₂O, Sigma-Aldrich, St. Louis, US), cumene hydroperoxide (contains 20 % aromatic hydrocarbon, TCI, Tokyo, JP), *tert*-butyl hydroperoxide (70 % in water, TCI, Tokyo, JP), 1,2-(methylenedioxy)-4-nitrobenzene (NBD, 98 %, Sigma-Aldrich, St. Louis, US), naphthalene (99 %, Sigma-Aldrich, St. Louis, US), (*R*)-(-)-1-Indanol (99 %, Sigma-Aldrich, St. Louis, US), (*S*)-(+)-1,2,3,4-tetrahydro-1-naphthol (98 %, TCI, Tokyo, JP), 1,2,3,4-tetrahydronaphthalene (99 %, Fluka, Buchs, CH), 1-indanone (99 %, Sigma-Aldrich, St. Louis, US), indane (95 %, TCI, Tokyo, JP), 1-hydroxyindane (99 %, TCI, Tokyo, JP), α -tetralone (96 %, Fluka, Buchs, CH), 2-methylnaphthalene (97 %, Sigma-Aldrich, St. Louis, US), 2-naphthaldehyde (98 %, TCI, Tokyo, JP), 2-hydroxymethylnaphthalene (97 %, abcr, Karlsruhe, DE), 1-methylnaphthalene (96 %, TCI, Tokyo, JP), 2-methyl-1,4-naphthoquinone (98 %, Sigma-Aldrich, St. Louis, US), 1,4-naphthoquinone (97 %, Sigma-Aldrich, St. Louis, US), 2-methoxy-1,4-naphthoquinone (98 %, Sigma-Aldrich, St. Louis, US), 1,2,3,4-tetrahydro-1-naphthol (97 %, Sigma-Aldrich, St. Louis, US), 2-bromo-1,4-naphthoquinone (98 %, Sigma-Aldrich, St. Louis, US), 4-octanone (98 %, TCI, Tokyo, JP), 2-methoxynaphthalene (98 %, TCI, Tokyo, JP), 2-bromonaphthalene (97 %, Fluka, Buchs, CH). As a buffer system, 50 mM potassium phosphate (KPi) pH 7 was utilised as an aqueous phase for the bioconversions.

Gas chromatography-mass spectrometry (GC-MS). Measurements were performed on a Shimadzu GCMS-QP2020 NX instrument (Shimadzu, Kyoto, JP) with a Lipodex E column (25 m x 0.25 mm, Macherey-Nagel, Düren, DE) for the chiral and on an SH-Rxi-5Sil MS (30 m x 0.25 mm, Shimadzu, Kyoto, JP) for the achiral measurements, whereas helium was utilised as the carrier gas. The samples were injected splitless (1 μ l) with a liner temperature of 280 °C. The interface temperature was set to 290 °C. Ionisation was obtained by electron impact with a voltage of 70 V, and the temperature of the ion source was 250 °C. The oven temperature profile for each compound is shown in Table S2. The detector voltage of the secondary electron multiplier was adjusted in relation to the tuning results with perfluorotributylamine. The GC-MS parameters were controlled with GCMS Real Time Analysis, and for data evaluation, GCMS Postrun Analysis (GCMSsolution Version 4.45, Shimadzu, Kyoto, JP) was used. Calibration and quantification were implemented in SIM (selected ion monitoring) mode with the corresponding *m/z* traces as shown in Table S2 in triplicates. As internal standard 4-octanone (1 mM, *m/z* 128) in EtOAc was utilised. The product formation of 5-Methyl-1,4-naphthoquinone (**3a**) was confirmed by the consistent literature fragmentation pattern⁴⁶: MS (EI) *m/z* 172, 144, 118, 116, 115, 90. For product quantification of 5-methyl-1,4-naphthoquinone (**3a**), 6-methoxy-1,4-naphthoquinone (**4a**, MS (EI) *m/z*: 188, 160, 134, 106, 63) and 6-bromo-1,4-naphthoquinone (**5a**, MS (EI) *m/z*: 384, 382, 296, 294, 266, 264, 73) the corresponding structural isomers menadione (**2a**), 2-methoxy-1,4-naphthoquinone (**4b**) and 2-bromo-1,4-naphthoquinone (**5b**) were utilised. Compound **1b** was derivatised according to the standard procedure of Macherey-Nagel (Düren, DE) with BSTFA: therefore the water was removed by an Eppendorf concentrator 5301 (Hamburg, DE) under vacuum at 60 °C for 1.5 h. The resulting residue was dissolved in 100 μ l pyridine with ultrasound for five minutes, followed by addition of 100 μ l BSTFA. The

derivatisation reaction was accomplished at 80 °C for 20 min and the solution was directly utilised for GC-MS analysis resulting in the literature known fragmentation pattern⁴⁷: MS (EI) m/z 231, 203.

Single site saturation mutagenesis. Mutagenesis was performed using the Golden Mutagenesis technique³⁶ combined with the “22c-trick”⁴⁸ for residue randomisation. The *Mth*UPO wildtype gene combined with a *Sce*- α Galactosidase signal peptide at the *N*-terminus and a TwinStrep-GFP11 purification/detection tag at the *C*-terminus was chosen as genetic template³⁶ targeting the following amino acid residues within the active site or the entrance channel for randomisation: L56, F59, L60, L86, F154, T155, S159, A161, L206. As backbone structure, the expression plasmid pAGT572_Nemo 2.0 was utilised, enabling bacterial antibiotic selection (ampicillin resistance) and yeast auxotrophy selection (URA3 marker). As a placeholder for the target gene sequence, a lacZ cassette (approx. 600 bp) is integrated, which enables β -galactosidase based blue/white selection of transformants based on the conversion of X-Gal. For the mutagenesis, the Golden Mutagenesis protocol was applied.³⁶ The resulting Golden Gate setup mixture was transformed in chemically competent *E.coli* DH10B cells. After heat shock transformation (90 seconds at 42 °C) and recovery (1h at 37 °C) the mixture (approx. 320 μ L) was split into two fractions, 60 μ L were plated on selective LB agar plates (50 μ g \times mL⁻¹ X-Gal; 100 μ g \times mL⁻¹ carbenicillin; 150 μ M IPTG) and the remaining volume used to directly inoculate 4 mL TB Medium (100 μ g \times mL⁻¹ carbenicillin). The plasmid DNA mixture was isolated from the liquid culture using a NucleoSpin Plasmid Kit (Macherey-Nagel, Düren, DE). The efficiency of the Golden Gate reaction was evaluated based on the performed blue/white screening and the Golden Mutagenesis analysing feature “Quick Quality Control”⁴⁹ monitoring the codon distribution at the previously mentioned positions. The resulting plasmid DNA

mixture was then transformed into chemically competent yeast cells (INVSc1 strain) by polyethylene glycol/lithium acetate transformation. For transformation, an amount of 100 ng of the plasmid preparation was added to 10 μ L of salmon sperm DNA (10 mg/mL; Sigma Aldrich, Hamburg, DE) and mixed. This mixture was then added to a thawed aliquot of INVSc1 cells on ice. 600 μ L of transformation buffer (40 % (v/v) poly ethylene glycol 4000; 100 mM lithium acetate; 1 mM EDTA; 10 mM Tris-HCl pH 7.4) were added and the cells incubated under rigid shaking (30 °C; 850 rpm) for 30 min. Afterwards, 70 μ L of pure DMSO were added and the cells incubated for a further 15 min at 42 °C without shaking. Finally, the cells were precipitated by short centrifugation, the supernatant discarded, and the cell pellet resuspended in 350 μ L sterile ddH₂O. Different volumes were plated on Synthetic Complement (SC) Drop Out plates supplemented with 2 % (w/v) glucose as carbon source and lacking Uracil as an auxotrophic selection marker. Plates were incubated for at least 48 hours at 30 °C till clearly background distinguishable white colonies appeared.³⁶

Double site saturation mutagenesis. The single-site saturation mutagenesis led to the identification of relevant amino acid residues, which were combined in a double site saturation mutagenesis approach based on spatial proximity and their potential interactions. The positions L60/F154, I52/A57, F59/L150, S159/A161, F63/L86, were therefore simultaneously randomised using an NDT codon degeneracy utilising the previously mentioned Golden Mutagenesis protocol.

Generation of a recombination library of the best performing variants. The best performing variants from the single, as well as from the double site saturation mutagenesis were chosen for recombination. For this approach, the best performing amino acid residues were selected and randomised. The following positions were chosen: L60 (WT/F/Q/M), F59 (WT/Q),

A57 (WT/I), F154 (WT/V/I), S159 (WT/G/N), A161 (WT/I/F). The library was generated based on the previously mentioned Golden Mutagenesis protocol yielding 864 possible combinations.

Microtiter plate cultivation of *S. cerevisiae*. For *Mth*UPO production in microtiter plate format specialised 96 half deep well plates were utilised. The model type CR1496c was purchased from EnzyScreen (Heemstede, NL) and plates were covered with fitting CR1396b Sandwich cover for cultivation. Plates and covers were flushed before every experiment thoroughly with 70 % ethanol and air-dried under a sterile bench until usage. In each cavity, 220 μ L of minimal expression medium were filled and inoculated with single, clearly separated yeast colonies using sterile toothpicks. The minimal selective expression medium (1x concentrated SC Drop stock solution lacking uracil, 2 % (w/v) galactose, 71 mM potassium phosphate buffer pH 6.0, 3.2 mM magnesium sulfate, 3.3 % (v/v) ethanol, 50 mg/L haemoglobin, 25 mg/L chloramphenicol) was freshly prepared out of sterile stock solutions immediately before each experiment, mixed and added to the cavities. After inoculation of the wells the plates were covered, mounted on CR1800 cover clamps (EnzyScreen) and incubated in a Minitron shaking incubator (Infors, Bottmingen, SUI) for 72 h (30 °C; 230 rpm). After cultivation, the cells were separated from the peroxygenase containing supernatant by centrifugation (3400 rpm; 45 min; 4 °C).³⁶ The cell pellet was resuspended in the remaining supernatant, and glycerol was added to achieve a final concentration of 25 % (v/v). The sealed microtiter plate was frozen by liquid nitrogen and stored at – 80 °C as mother plate for subsequent hit verification.

Activity Screening via NBD assay in microtiter plate format. The utilisation of 5-nitro-1,3-benzodioxole for a colourimetric screening approach has been described before yielding the

chromophore 4-nitrocatechol.^{35, 37} The conditions were slightly modified: after centrifugation 20 μ l of the supernatant from the microtiter plate cultivation was transferred to a polypropylene 96 well screening plate (Greiner Bio-One, Kremsmünster, AT) and 180 μ l of the master mix were added (end concentrations: 100 mM KPi buffer pH 7, 300 μ M NBD, 1 mM H₂O₂, 5 % (v/v) acetone). The absorption was detected for one hour at 425 nm (interval: 30 s) starting directly after the addition of the master mix at an absorbance reader (TECAN, Grödig, AT). The reaction endpoint was determined overnight. Improved *Mth*UPO variants were identified by comparing the absorption values of the NBD assay and the fluorescence values of the split-GFP assay with the parental variant.

Split-GFP assay. Protein normalisation was performed employing the principle of a split GFP normalisation assay as described by Santos-Aberturas *et al.*⁴¹ with slight modifications. The complementation fragment sfGFP 1–10 was cloned into the Golden Mutagenesis plasmid pAGM22082_cRed³⁶ for T7 promoter controlled expression in *E.coli*. For measurement 20 μ l of yeast expression supernatant was transferred to a previously BSA blocked 96 well Nunc MaxiSorp Fluorescence plate (ThermoFisherScientific, Waltham, US) and 180 μ l of sfGFP 1–10 inclusion body preparation added. Immediate fluorescence values (GFP fluorophore: excitation wavelength: 485 nm; emission wavelength: 535 nm; top read mode) was measured using a 96 well plate fluorescence reader (TECAN, Grödig, AT). After storage over two nights (at 4 °C) final fluorescence values were measured. Protein quantities were then normalised based on the relative fluorescence increase (differential values) and in comparison to the empty plasmid backbone. Based on the split-GFP assay, the percentage of secreted variants could be calculated (Table S4).

Automated data evaluation and verification. For the microtiter plate screening, including the NBD and split-GFP assay, an automated data evaluation by R Studio was utilised. Thereby, the best performing variants were identified based on their respective endpoint after one hour and overnight, their NBD slope and their NBD/GFP correlation when compared to the parental variant. For the data verification, the best performing variants were reproduced in a microtiter plate setup in triplicates. If the improved activity was confirmed, the protein was cultivated in shake flask scale and purified for further characterisation.

Shake flask cultivation and protein purification. For the preculture 50 mL of SC Drop out selection media (+ 2 % (w/v) Raffinose as non-repressible carbon source and 25 mg/L chloramphenicol) was inoculated with one single colony derived from a selection plate (SC Drop; -Uracil) and grown for 48 h (30 °C; 160 rpm; 80 % humidity). The main expression culture was inoculated with a starting optical density of 0.3. For large scale peroxygenase production rich non-selective expression medium (20 g/L peptone; 10 g/L yeast extract; 2 % (w/v) galactose; 71 mM potassium phosphate buffer pH 6.0; 3.2 mM magnesium sulfate; 3.3 % (v/v) ethanol; 25 mg/L chloramphenicol) was utilised. Cultivation was performed in 2.5 L Ultra yield flasks (Thomson Instrument, Oceanside, US) in a final culture volume of 500 mL per flask after sealing the flask with breathable Aeraseal tape (Sigma Aldrich, Hamburg, DE) allowing for gas exchange. The main cultures were incubated for further 72 h (25 °C; 110 rpm; 80 % humidity). After cultivation, the cells were separated from the peroxygenase containing supernatant by centrifugation (4300 rpm; 35 min; 4 °C). The supernatant was concentrated approx. 10-fold using ultrafiltration. Therefore a Sartocoon Slice 200 membrane holder (Sartorius, Göttingen, DE) was equipped with a Sartocoon Slice 200 ECO Hydrosart Membrane (10 kDa nominal cut-off; Sartorius) within a self-made flow setup. The flow system for ultrafiltration was

operated by an EasyLoad peristaltic pump (VWR International, Darmstadt, DE). The cleared supernatant (500 mL) was concentrated to a volume of 50 mL, and 900 mL of purification binding buffer (100 mM Tris-HCl pH 8.0, 150 mM NaCl) were added as a buffer exchange step. This sample was then concentrated to a final volume of 50 mL. Protein purification was implemented utilising the C-terminal attached double Strep II Tag (WSHPQFEK), coined TwinStrep® (Iba Lifesciences, Göttingen, DE). As a column, Gravity Strep-Tactin®XT Superflow® columns (5 mL; Iba Lifesciences) were chosen. In the first step, the column was equilibrated with 5 column volumes (CVs) binding buffer. The concentrated sample (50 mL) was filter sterilised (0.2 µm syringe filter) and applied to the column. After application, the column was washed with 6 CVs binding buffer. Elution was performed based on binding competition with biotin, therefore approx. 2 CV of elution buffer (100 mM Tris-HCl pH 8.0, 150 mM NaCl; 50 mM biotin) were applied to the column. The pooled elution fraction was then dialysed overnight (4 °C) against 5 L of storage buffer (100 mM potassium phosphate pH 7.0) using ZelluTrans dialysis tubing (6-8 kDa nominal cut-off; Carl Roth).³⁶ The enzyme concentration of the dialysed samples was determined by colourimetric BCA assay utilising a Pierce™ BCA Protein Assay Kit (ThermoFisherScientific, Waltham, US) following the instructions of the manufacturer. The samples were stored at – 20 °C until further utilisation.

NBD assay with purified enzyme for TOF/TON determination. The purified *Mth*UPO variants were measured via the NBD assay under the following conditions: 20 nM *Mth*UPO variant (exception: F59Q/L60F/S159G with 10 nM), 300 µM NBD, 1 mM H₂O₂, 100 mM KPi buffer (pH 7), 5 % acetone (v/v). The turnover numbers (TON), turnover frequency values and conversions were determined after 1h. For determination of the catalytic performance, the TON, TOF and conversion were calculated based on the corrected extinction coefficient of 4-

nitrocatechol. The actual extinction coefficient was calculated by a calibration curve of 4-nitrocatechol in 100 mM KPi buffer (pH 7) with 5 % acetone (v/v) (Figure S2a) leading to $\epsilon_{425\text{nm}, 4\text{-nitrocatechol}} = 11289 \text{ M}^{-1}\cdot\text{cm}^{-1}$. This coefficient was corrected by the extinction coefficient of NBD $\epsilon_{425\text{nm}, \text{NBD}} = 419 \text{ M}^{-1}\cdot\text{cm}^{-1}$ (Figure S2b) yielding to the corrected coefficient of $\epsilon_{425\text{nm}, \text{corr}} = 10870 \text{ M}^{-1}\cdot\text{cm}^{-1}$, which can be utilised for the catalytic performance calculations:

$$TON = \frac{[product]}{[catalyst]} \left[\frac{mol}{mol} \right]$$

$$TOF = \frac{TON}{time} [min^{-1}]$$

Determination of kinetic parameters. To determine the kinetic parameters K_m and k_{cat} , the purified protein samples were utilised. The best performing variants from the NBD screening were compared to each other: The enzyme concentration was set to 20 nM for each variant for the K_m (NBD) determination. The only exception was variant L60F where an enzyme concentration of 5 nM was used. For the determination of the K_m for H_2O_2 20 nM enzyme concentration were employed for all protein variants. For the K_m determination of the corresponding substrate, the second substrate was utilised in its saturation concentration. The velocity quantification was achieved in the linear range of the 4-nitrocatechol using the corrected $\epsilon_{425\text{nm}, \text{corr}} = 10870 \text{ M}^{-1}\cdot\text{cm}^{-1}$ by applying automated pathlength correction in the microtiter plate. The nonlinear regression using the Michaelis-Menten model was performed with the aid of Sigmaplot (Version 14.0, Germany) yielding kinetic parameters v_{max} , K_m , R^2 .

Thermostability measurements. Thermostability measurements of the purified enzymes were performed by Differential Scanning fluorimetry (DSF) on a Prometheus NT.48 nanoDSF instrument (NanoTemper Technologies GmbH, München, DE) in storage buffer (100 mM Tris-

HCl pH 7.0). Approximately 10 μ L of sample volume were loaded into a Prometheus NT.48 High Sensitivity Capillary (NanoTemper Technologies GmbH). Protein unfolding was subsequently monitored by following the ratio of intrinsic protein tyrosine and tryptophan fluorescence at 350 nm to 330 nm over time, increasing the temperature from 20 $^{\circ}$ C to 95 $^{\circ}$ C with a heating ramp of 1 $^{\circ}$ C per minute. The melting temperature corresponds to the maximum of the first derivative of the 350/330 nm ratio. All measurements were performed at least in triplicates.³²

Initial oxyfunctionalisation comparison between *Mth*UPO and the best performing variants from the NBD assay. For the identification of the best performing variant towards the hydroxylation of naphthalene and its derivatives, an initial approach with direct addition of H₂O₂ (without a syringe pump setup) was chosen. The following conditions were adjusted: 500 nM *Mth*UPO variant, 1 mM H₂O₂, 1 mM of the corresponding substrate (see Figures S6-S8), 100 mM KPi pH 7, 1 h at 25 $^{\circ}$ C. The reaction was quenched by the addition of 400 μ l *n*-hexane with benzyl alcohol as the internal standard. Corresponding samples were analysed in the GC/MS scan mode, and the products were identified by library comparison. For quantification and product confirmation, the syringe pump setup was utilised.

Bioconversion of naphthalene and naphthalene derivatives by a syringe pump system. With a syringe pump system, the product formation could be increased compared to the direct addition of H₂O₂ (initial approach). The conditions were adjusted for each reaction setup and are shown in Table S7. For the H₂O₂ addition, a programmable syringe pump from Chemyx Inc. (Model: Fusion 101R, Stafford, US) was utilised. The reaction and addition were performed under continuous stirring at room temperature. The extraction was accomplished by the addition

of 400 μ l of EtOAc (containing 1 mM 4-octanone as internal standard) at the end of the reaction. After 30 s of vortexing, the organic layer was transferred for GC/MS analysis.

Bioconversion of indane and 1,2,3,4-tetrahydronaphthalene. For the bioconversion of these substrates, no syringe pump system was needed. The reaction was started by addition of H₂O₂. The hydroxylation and overoxidation to the ketone were performed under the following conditions: 100 nM L60F, 1 mM indane, 1 mM H₂O₂, 100 mM KPi pH 7, 5 % acetone (v/v), 1 h at 25 °C in triplicates. For the hydroxylation of 1,2,3,4-tetrahydronaphthalene, the conditions were adapted from the indane bioconversion. The best performing overoxidation of 1,2,3,4-tetrahydronaphthalene to the α -tetralone was accomplished by *MthUPO* F59Q/L60M/S159G/F154A with a final concentration of 2 mM H₂O₂. The extraction was achieved by the addition of 400 μ l of EtOAc (containing 1 mM 4-octanone as internal standard) at the end of the reaction. After 30 s of vortexing, the organic layer was transferred for GC/MS analysis. Quantification of the products were carried out on an SH-Rxi-5Sil MS column under the previously mentioned GC/MS conditions. The *ee* determination was carried out on a Lipodex E column.

Homology model and Molecular Dynamics (MD) simulations. Homology model for *MthUPO* structure (245 AA, + TwinStrep-GFP11 tag) has been constructed based on the solved crystal structure of the UPO from *Marasmius rotula* (*MroUPO*, PDB: 5FUJ, 35.1 % identity) using the homology server SWISS-MODEL.⁵⁰ The resulting homology model has been further refined with extensive MD simulations based on 5 independent replicas of 1000 ns each, accumulating a total of 5 μ s of simulation time. MD simulations in explicit water were performed using the AMBER18 package.⁵¹ Parameters for the different substrates (5-Nitro-1,3-benzodioxole (NBD), 2-methylnaphthalene, 1-methylnaphthalene, 2-methoxynaphthalene, and

indane) were generated within the antechamber⁵² module in AMBER18 package using the general AMBER force field (gaff),⁵³ with partial charges set to fit the electrostatic potential generated at the B3LYP/6-31G(d) level by the RESP model.⁵⁴ The charges were calculated according to the Merz–Singh–Kollman scheme^{55,56} using the Gaussian 09 package. Parameters for the haem Cpd I and the axial Cys were taken from reference.⁵⁷ The protein was solvated in a pre-equilibrated cubic box with a 12-Å buffer of TIP3P⁵⁸ water molecules using the AMBER18 leap module, resulting in the addition of ~17,500 solvent molecules. The systems were neutralised by addition of explicit counterions (Na⁺ and Cl⁻). All subsequent calculations were done using the AMBER force field 14 Stony Brook (ff14SB).⁵⁹ A two-stage geometry optimisation approach was performed. The first stage minimises the positions of solvent molecules and ions imposing positional restraints on solute by a harmonic potential with a force constant of 500 kcal mol⁻¹ Å⁻², and the second stage is an unrestrained minimisation of all the atoms in the simulation cell. The systems were gently heated using six 50 ps steps, incrementing the temperature by 50 K for each step (0–300 K) under constant-volume and periodic-boundary conditions. Water molecules were treated with the SHAKE algorithm such that the angle between the hydrogen atoms was kept fixed. Long-range electrostatic effects were modelled using the particle-mesh-Ewald method.⁶⁰ An 8 Å cutoff was applied to Lennard–Jones and electrostatic interactions. Harmonic restraints of 30 kcal·mol⁻¹ were applied to the solute, and the Langevin equilibration scheme was used to control and equalise the temperature. The time step was kept at 1 fs during the heating stages, allowing potential inhomogeneities to self-adjust. Each system was then equilibrated for 2 ns with a 2 fs time step at a constant pressure of 1 atm and temperature of 300 K without restraints. Once the systems were equilibrated in the NPT ensemble, production trajectories were then run under the NVT ensemble and periodic-boundary

conditions. In particular, a total of 5000 ns for wildtype *MthUPO* were accumulated from 5 independent replicas (1000 ns each); Finally, a total of 750 ns from 3 independent replicas were accumulated for L60F and L60F/S159G/A161F variants (250 each). An extensive conformational sampling based on long timescale MD trajectories (1,000 ns) and 5 different MD replicas for wildtype *MthUPO* has been carried out to refine the initial homology model. From this accumulated simulation time, the most representative structure visited by *MthUPO* was obtained by clustering analysis based on the protein backbone RMSD. This representative structure was used for further MD simulations and analyses of the other studied variants. Trajectories were processed and analyzed using the cpptraj⁶¹ module from AmberTools utilities.

Docking and protocol used for substrate bound MD simulations. Docking calculations were performed using AutoDock Vina.⁶² The most populated clusters (based on backbone clustering analysis) obtained from MD simulations carried out in the apo state were used, and docking predictions were then utilised as starting points for substrate-bound MD simulations. To avoid substrate diffusion outside the enzyme active site and to sample catalytically competent binding poses, a $100 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{\AA}^{-2}$ restraint is applied when the distances between the center of mass of the substrate and the O atom of the Fe=O in Cpd I are greater than 6Å (for indane) or 6.7Å (for naphthalene derivatives). No restraints were used in NBD substrate-bound simulations. Same protocol for MD simulations described above has been employed, accumulating a total of 300 ns of production trajectories from 3 independent replicas for all substrate-bound studied.

Quantum Mechanics (QM) calculations. Density Functional Theory (DFT) calculations were carried out using Gaussian09.⁶³ Geometry optimisations and frequency calculations were

performed using (U)B3LYP⁶⁴⁻⁶⁶ functional with 6-31G(d) basis set on all atoms. The stationary points were verified as minima by a vibrational frequency analysis. Enthalpies and entropies were calculated for 1 atm and 298.15 K. Single point energy calculations were performed using the functional (U)B3LYP with the Def2TZVP basis set on all atoms, and within the CPCM polarisable conductor model (dichloromethane, $\epsilon = 8.9$)^{67, 68} to have an estimation of the dielectric permittivity in the enzyme active site.⁶⁹ Bond Dissociation Energies (BDEs) were calculated as the standard enthalpic change of the following process at 298 K (Indane \rightarrow Indane \cdot + H \cdot), which provides an estimation of the strength of the C-H bond under study. Different electronic states (singlet close-shell for indane and doublet for both radical species) have been considered.

Within this chapter, single site saturation mutagenesis libraries of *MthUPO* have been investigated with the aid of an expanded version of the previously introduced MISER GC-MS analysis technique. Nine active site/heme channel residue libraries have been assessed for the one-pot conversion of three non-activated substrates, namely octane, cyclohexane and cyclohexene. Further expansion of the MISER GC-MS technique allowed for the simultaneous analysis of six distinct reaction products within a 96 well plate high throughput setup. Despite screening a rather small number of enzyme variants (approx. 900), several relevant shifts in product formation could be obtained. Especially the enzyme variant A161L proved to be a highly interesting starting point for further investigations. Employing this enzyme variant, a significant amount of 1-octanol is formed (38 % of total products), a reaction product not accessible when using the wild type enzyme. Variant A161L furthermore enabled higher substrate conversion and improved stereoselectivity in the conversion of 1-methyl-1-cyclohexene.

rsc.li/catalysis

A high throughput GC-MS approach was developed, permitting the simultaneous analysis of up to three substrates and six products quantitatively from one reaction mixture. This screening approach was applied to site-saturation libraries of the novel unspecific peroxygenase *Mth*UPO. Using this setup enabled substantial insights from a small mutant library. Enzyme variants were identified exhibiting selective alkene epoxidation and substantially shifted regioselectivities to 2- and 1-octanol formations. Computational modelling rationalised the observed selectivity changes.

Introduction

Fungal unspecific peroxygenases (UPOs) were discovered in 2004^{1–6} and can hydroxylate an extensive substrate scope.^{7,8} Contrary to the phylogenetically related chloroperoxidases,⁹ UPOs can hydroxylate non-activated aliphatic sp³-carbons. Epoxidation of C=C double bonds is also observed for UPOs. The mechanism performs *via* the activation of hydrogen peroxide by the iron-heme centre. Upon releasing a water molecule, the oxyferryl Fe(IV)=O porphyrin cation radical compound I (Cpd I) is formed. This reactive species can perform oxyfunctionalisations (Scheme 1).³

Using this enzyme mechanism for the selective hydroxylation of non-activated carbons is of utmost interest. Thus far, the performed studies on UPOs towards aliphatic hydroxylation reactions were mainly limited to wildtype UPO enzymes and a yeast expression UPO variant.^{2,4–6,10–12} Although previously demonstrated UPO activities are impressive, their hampered regio- and chemoselectivities represent a limitation for their synthetic and industrial application. This limitation was recently addressed for the first time by combining computational modelling and mutagenesis and led to *Mro*UPO (from *Marasmius rotula*) and *Cvi*UPO (from *Collariella virescens*) variants with improved

chemoselectivities.^{13,14} Also, recent work in our laboratory addressed this issue by creating chemodivergent variants of *Mth*UPO from *Myceliophthora thermophila* for benzylic or aromatic oxyfunctionalisations.³⁰

To harness the impressive activities of UPOs for chemo- or regioselective transformations, protein engineering approaches and directed evolution techniques are of particular interest. Directed evolution consists of random or semi-rational mutagenesis to create enzyme libraries assessed for improved enzyme abilities by high throughput analysis. Beneficial mutations are selected and subjected to further rounds of mutagenesis and analysis. This method is extremely successful and has led to the engineering of many selective enzymes.^{15–17}

Two technologies are required to perform protein engineering for regio-, and chemoselective hydroxylation reactions using UPOs: a microtiter plate-based enzyme production setup and a high throughput assay, which is able to differentiate between various functional isomers and regioisomers.

The development of heterologous UPO expression systems in the yeast organisms *Saccharomyces cerevisiae* and *Pichia pastoris* enabled the UPO production in sufficient amounts using a microtiter plate setup.^{18–20,29} The remaining challenge was the development of a suitable and versatile assay system.

In the last two decades, substantial progress was made towards the design of smaller but smarter enzyme libraries in the protein engineering field. This is mostly due to significant time and money constraints associated with large mutant libraries' assessment. Advances were achieved by focussing the mutagenesis on specific regions, like the active site or the substrate entrance channel.^{21,22} Another approach

† Electronic supplementary information (ESI) available. See DOI: 10.1039/d0cy02457k

is to limit the available amino acid alphabet to solely include functionally relevant residues.^{23,24} These extremely successful developments vastly increased the applicability of directed evolution.

Further potential to increase the “smartness” of mutant libraries is by assessing the maximum information of the created variants. Fasan and co-workers approached this by generating a focussed P450 library and screened it with several substrates consecutively. This “fingerprinting method” generated substantially more insights and knowledge about the mutated positions and discovered specific enzyme variant/substrate pairs.²⁵

We hypothesised that screening an enzyme library with the simultaneous assessment of several substrates and products would provide a new dimension to the obtainable insights. The gained knowledge would be $[(n - 1) + (m - 1)]$ -fold increased relative to the assessment of one substrate/product pair, where n is the number of substrates and m the number of quantified products. A tool to permit screenings of this kind would be our recently reported, substrate-independent high throughput analysis with an off-the-shelf GC-MS (gas chromatography-mass spectrometry).²⁶ This method enabled the quantification of an internal standard, the product and the byproduct simultaneously based on the MS separation within the mass analyser (quadrupole) with sample injection intervals of 33 s.

Further expanding this method could enable the assessment of product distributions for different functional isomers with different masses like alkene epoxidation vs allylic hydroxylation, and to differentiate regioisomeric products with the same mass, permitting protein engineering for regioselectivity.

The possible challenge of the simultaneous screening of multiple substrates is the potential inhibitory effect creating false negative results. However, this effect would be

comparable to the natural evolution where a vast number of similar substrates were available resulting in highly specialised and specific biocatalysts.

In the present work, we demonstrate the screening of 900 transformants with 3 substrates, 6 products, and one internal standard simultaneously (Fig. 1A). The optimised GC-MS technique proved to be able to differentiate between regioisomers and functional isomers for the substrates octane, cyclohexane and cyclohexene. By only screening a small focused library, three UPO variants with significantly modified regio- and chemoselectivity were identified.

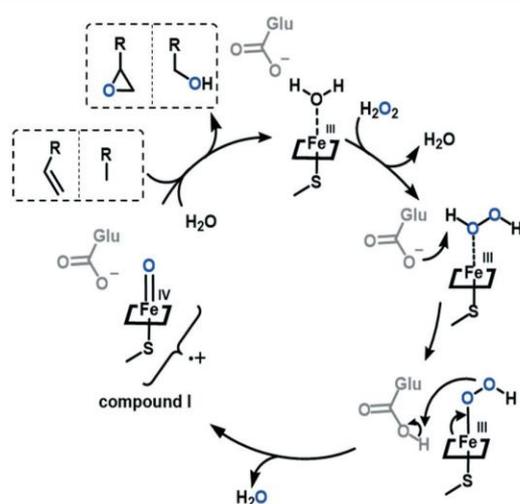

Results and discussion

We started our technology development using our previous multiple injections in a single experimental run (MISER) GC-MS method.²⁶ As this method already provided the simultaneous assessment of three analytes, we further challenged the system by employing it to determine the cyclohexene epoxidation/allylic hydroxylation as well as the cyclohexane hydroxylation. Since the MISER GC-MS technique relies on analyte quantification *via* MS analysis, it is vital that all possible products exhibit different masses. As epoxides tend to derivatise in the GC-liner, we increased the robustness of the setup by performing an acidic workup. This opens the epoxides and forms the stable halohydrins.

Since non-activated C–H bonds represent the most challenging compounds for selective oxyfunctionalisations, we considered the bioconversion of octane as a model substrate. Its hydroxylation led to three different regioisomers: 2-, 3- and 4-octanol—all having the identical mass. Additionally, the formed alcohols tend to fragment by electron impact ionisation (Fig. S2†). The resulting small fragments cannot be quantified by MS in complex biological matrices. To allow the simultaneous analysis and quantification of the different octanol regioisomers the enzymatic products were derivatised by *N*-trimethylsilylimidazole (TSIM) to generate the respective silylethers. We were pleased to observe that the increased masses led to regioselective fragmentation during electron impact ionisation (Fig. 1B). The specific fragmentation permitted the detection, differentiation and quantification of the generated products within the MISER-GC-MS setup (Fig. 1 and S1†).

To compare the MS response and to rule out ion suppression effects of the three octanols and the oxyfunctionalised cyclohexane and cyclohexene products (including the internal standard), the MS response of the seven compounds was analysed individually and as compound mixture in the MISER-GC-MS approach. The single and multiple analyte measurements revealed a linear response thereby verifying the feasibility of the envisioned simultaneous quantification setup (Fig. S3†).

With the ability of the simultaneous analysis of seven compounds in hand, we expanded the workflow to a microtiter plate setup including the following steps: i) microtiter plate cultivation of *S. cerevisiae* expressing the

Scheme 1 Proposed mechanism for UPOs catalysing alkane and alkene oxyfunctionalisations.

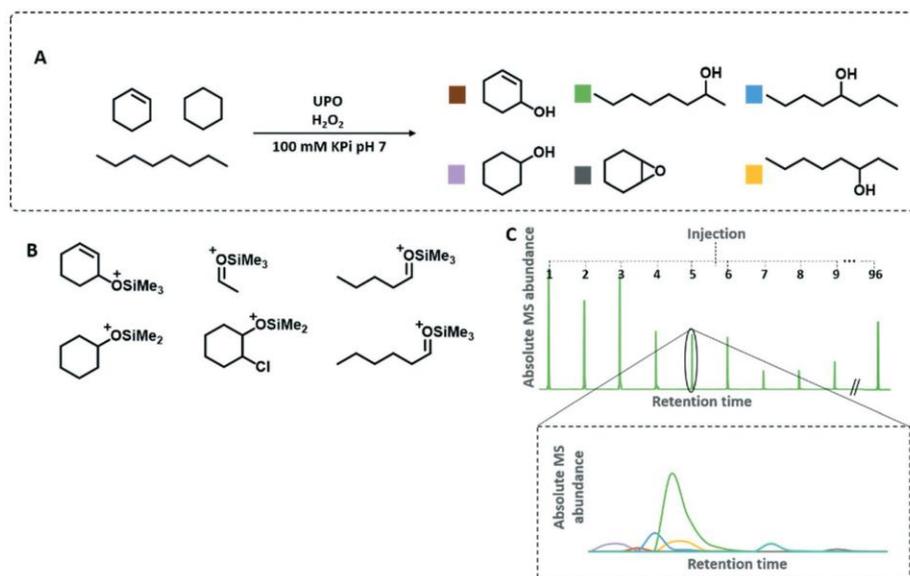

Fig. 1 A) UPO catalyzed one pot conversion of octane, cyclohexane and cyclohexene (1 mM H₂O₂, 5 mM of each substrate, 5% (v/v) acetone, 100 mM KPi pH 7, 1 h reaction time at 25 °C using 100 μ l of the microtiter plate cultivated *S. cerevisiae* supernatant containing the corresponding UPO variant). B) Regiospecific mass fragmentation during the ionisation and C) MISER-GC-MS chromatogram of an injected microtiter plate detecting quantitative product amounts of the regio- and chemospecifically formed products.

respective UPO variant, ii) bioconversion of the substrates octane, cyclohexane and cyclohexene by the secreted UPO variant, iii) acidic ring-opening of the epoxide leading to halohydrins, iv) extraction with *n*-hexane, v) derivatisation of the alcohols with the silylation agent TSM, vi) washing with

water to dispose the emerged imidazole and vii) injection of the 96-well plate samples into the isothermal MISER-GC-MS run (Fig. 1C). The entire MISER-GC-MS workflow was applied for 96 biological replicates yielding a standard deviation of <12% (Table S3[†]).

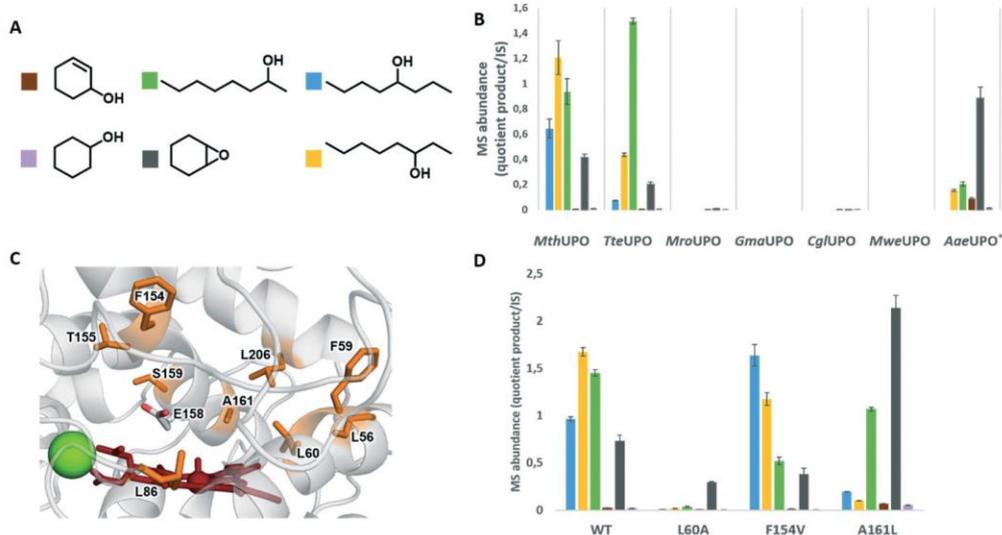

Fig. 2 Multiple substrate/product screening of UPOs cultivated in microtiter plate format A) colour legend for the different products, B) comparison of product distribution of several UPOs and C) active site of *MthUPO* with sites modified by saturation-mutagenesis (highlighted in orange), Mg²⁺ ion (green sphere) and haem species (red). D) *MthUPO* variants with shifted chemo- and regioselectivity. UPO catalyzed one pot conversion of octane, cyclohexane and cyclohexene (1 mM H₂O₂, 5 mM of each substrate, 5% (v/v) acetone, 100 mM KPi pH 7, 1 h reaction time at 25 °C using 100 μ l of the microtiter plate cultivated *S. cerevisiae* supernatant containing the corresponding UPO variant).

To select a UPO with the feasibility to convert unactivated or less activated substrates, we investigated the bioconversions of octane, cyclohexane and cyclohexene with a panel of heterologously expressed UPOs (Fig. 2B). UPO secreting *S. cerevisiae* transformants were cultivated in 96-well microtiter plates and the corresponding supernatant assessed for their biotransformation. The UPOs from *Galerina marginata* (*Gma*UPO) and *Marasmius wettsteinii* (*Mwe*UPO) showed no activity, whereas slight activity was detected for the UPOs from *Marasmius rotula* (*Mro*UPO) and *Chaetomium globosum* (*Cg*UPO). However, for these four UPOs the secretion levels were by far the lowest²⁰ and are hence not suitable for the desired workflow in microtiter plates. The engineered yeast-secretion variant *Aae*UPO* (also referred to as PaDa-I or rAaeUPO in the literature) from *Agrocybe aegerita*¹⁸ demonstrated a pronounced epoxide formation of cyclohexene, allylic hydroxylation, 2- and 3-octanol formation. The highest activities were displayed by the recently discovered *Mth*UPO from *Myceliophthora thermophila* and *Tte*UPO from *Thielavia terrestris*. Whereas *Mth*UPO showed substantial amounts of 2-, 3- and 4-octanol as well as the epoxide, *Tte*UPO revealed already a selectivity towards 3- and 2-octanol and decreased activities on the epoxide formation. Cyclohexanol formations were detected only in small amounts for all tested UPOs. As *Mth*UPO exhibited the lower regioselectivity but slightly increased activity for octane oxidation, we selected this UPO for our protein engineering endeavour.

We started our chemo- and regioselectivity fingerprint studies by investigating the active site using a homology model (Fig. 2C). We aimed to gain the maximum knowledge from a small library within one mutagenesis round and independently saturated nine active site residues with all canonical amino acids: L56, F59, L60, L86, F154, T155, S159, A161 and L206. The mutagenesis was performed using the Golden Mutagenesis cloning technique and its web tool for primer design.²⁷ The mutant library was transformed into *S. cerevisiae*, assessing around 900 transformants.

Gratifyingly, the applied high throughput screening with multiple substrates resulted in the emergence of three variants with significantly modified product distribution: L60A, F154V and A161L (Fig. 2D). Considering the aliphatic and hydrophobic nature of the screened substrates, it is not surprising that all positions were substituted with amino acids harbouring aliphatic side chains. Position F154 and A161 are located within the α -7-helix located above the peroxy-iron complex (Fig. 2C). Whereas A161 is located deeper in the active site, F154 is directly placed in the substrate entrance channel. L60 is found in the active site near the iron centre in a strategic position that could be important to modulate the substrate's approach to the Cpd I species in a reactive binding pose.

A clear shift in octanol regioisomer formation is observed within the multiple substrate screening for variants F154V and A161L. The wild type displayed the highest activity towards 3-octanol formation, followed by 2-octanol and then

4-octanol (Fig. 2D). Variant F154V modified that pattern and trended towards the 4-octanol formation. The most significant shift in regioselectivity for the octanol formation was discovered for variant A161L. According to the high throughput analysis, this variant substantially diminished the 4- and 3-octanol formation while preserving the 2-octanol regioisomer formation.

Besides the regioselectivity shifts for the octane hydroxylation, the bioconversions of cyclohexene and cyclohexane were simultaneously analysed. The primary screening data revealed substantially improved cyclohexene epoxidation by variant A161L while maintaining the high chemoselectivity with low allylic hydroxylations.

Additionally, we were very pleased to discover a selective variant for the epoxidation of cyclohexene over all the competing oxidation reactions. Variant L60A almost abolished the octane transformation but kept a significant cyclohexene oxide formation.

The screened library did not result in any significantly improved variant for cyclohexane hydroxylation or for a shifted cyclohexene oxidation pattern (from epoxidation towards allylic hydroxylation). It might be that additional positions or a combination of mutations (double or triple mutants) are required to access these activities. However, activation barriers for C–H abstraction by Cpd I estimated from density functional theory (DFT) model calculations (Fig. S12–S14†) already indicated that cyclohexane is intrinsically less reactive than cyclohexene epoxidation and octane C–H activation, respectively. DFT calculations also indicated that allylic C–H activation in cyclohexene is energetically less favourable than epoxidation (Fig. S13†).

With the successful screening of 900 transformants, we set our focus on verifying the observed selectivity shifts using purified *Mth*UPO variants and standard single substrate GC-MS analysis.

A syringe pump system was utilised for gradual hydrogen peroxide supply in a two-liquid-phase system with octane as the organic phase and the corresponding purified *Mth*UPO variant identified from the MISER-GC-MS screening. Variant F154V demonstrated 1.8-fold improved turnover numbers (TONs = mol product per mol enzyme) for formation of the 4-octanol (**1a**) regioisomer relative to the wildtype. Also, a 1.5 and 4-fold decreased formation of 3- (**1b**) and 2-octanol (**1c**), respectively, were observed (Fig. 3A and Table S4†), confirming the regioselectivity trend obtained by the GC-MS screening.

Variant A161L also proved the results from the primary screening. A 10-fold decreased formation of 4-octanol (**1a**) and no 3-octanol (**1b**) product was detected. However, the 2-octanol (**1c**) formation was even slightly increased. Most astonishingly, the single GC-MS analysis of variant A161L revealed the formation of 1-octanol (**1d**)—the least reactive position for C–H activation by Cpd I, as characterised by DFT calculations (Fig. S14†). 38% of the total octane hydroxylation product corresponded to 1-octanol (**1d**). The wild type or variant F154V display no activity for this transformation (Fig. S4†).

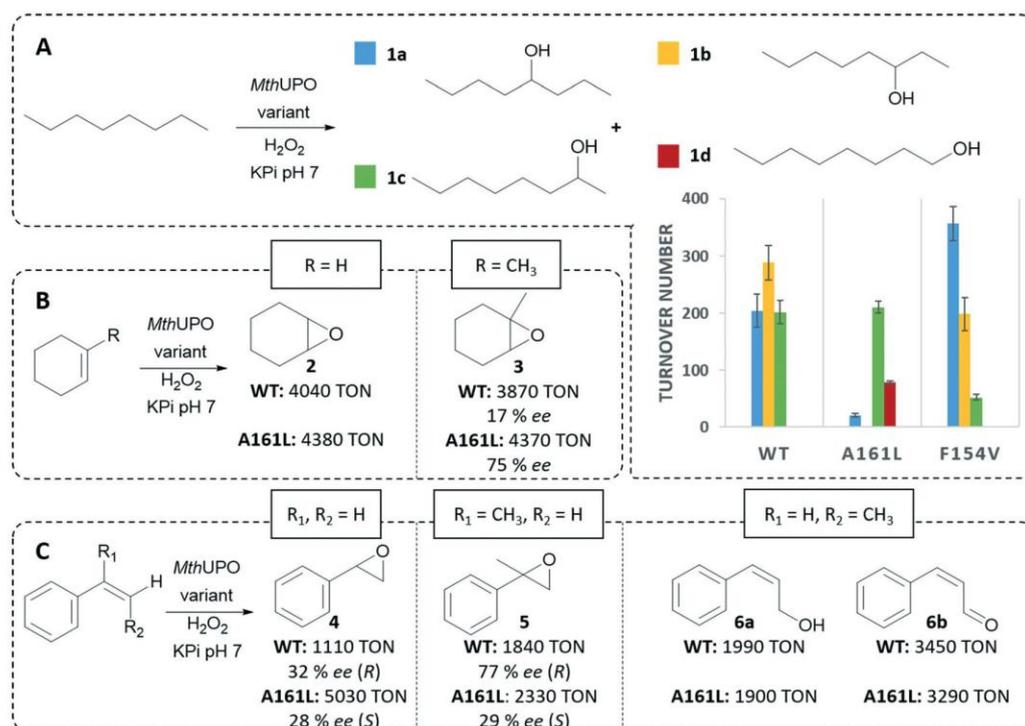

Fig. 3 A) Enzymatically catalysed conversion of octane and comparison of the by MISER-GC-MS identified *MthUPO* variants, B) cyclohexene and 1-methylcyclohexene bioconversion of *MthUPO* wildtype and A161L to the corresponding epoxide and C) styrene and styrene derivative bioconversion *MthUPO* wildtype and A161L (standard deviation <8%, reaction conditions for the syringe pump setup are in the ESI†).

Thus far, UPO's only reported ability to perform terminal hydroxylations on linear alkanes was reported for *MroUPO*, where the terminal alcohol was identified as an intermediate that was further oxidised to the corresponding carboxylic acid.¹²

In the case of *MthUPO* A161L, the variant exhibited no octanol overoxidation as no aldehyde or carboxylic acid were detected (Fig. S4†). This specificity further renders variant A161L highly significant.

To gain insights into the switch in the hydroxylation pattern observed due to the A161L mutation, we performed

molecular dynamics (MD) simulations as previously shown for UPOs.^{28,30} MD simulations with octane substrate bound in wild type *MthUPO* showed that the preferential binding conformation of octane corresponds to a buried mode that allows octane to maximise the hydrophobic interactions with multiple residues in the active site (L56, L60, F63, F154 and L206). Within this conformation, C4/C3 and C2 are accessible to Cpd I for the homolytic hydrogen abstraction from the C–H bond (Fig. 4 and S15 and S16†).

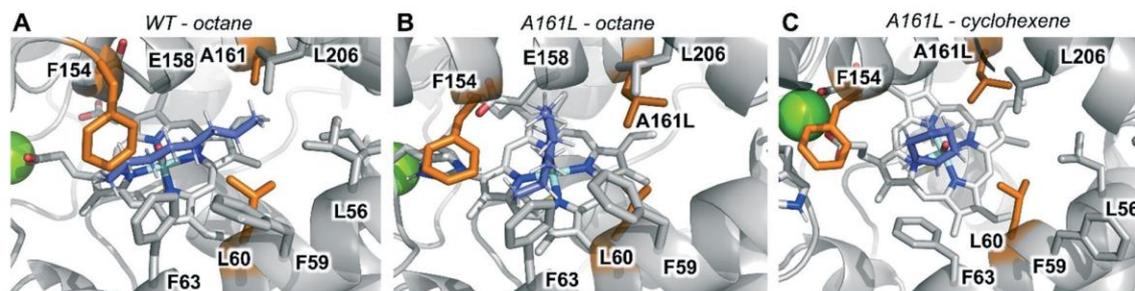

Fig. 4 Catalytically relevant binding modes as characterised from MD simulations with A) octane bound in wild type (WT) *MthUPO*; B) octane bound in A161L variant and C) cyclohexene bound in A161L variant. Substrates, haem cofactor and important active site and catalytic residues are shown in sticks format. The three mutated positions are highlighted in orange, substrates are shown in purple, and structural Mg^{2+} ion as a green sphere.

The inclusion of the bulkier A161L mutation in this inner active site position prevents the octane from binding deeper in the active site. It explores an additional conformation in which it partially occupies the entrance channel (Fig. 4 and S18†). From this new binding mode, in which octane is flanked by F59, F63, F159 and L206 residues, only the terminal positions C1/C2 can effectively approach the Cpd I catalytic species for hydroxylation.

We then focused on analysing the determined activities for cyclohexene. Variant A161L resulted in slightly improved TONs of 4380 compared to the wild type for the formation of the epoxide **2** in a two-liquid-phase system (Fig. 3B). MD simulations with cyclohexene bound in wild type and A161L variant indicated that the preferential and more buried binding pose explored by cyclohexene in the wild type is displaced towards occupying a binding position near the entrance channel in A161L variant (Fig. S19 and S20†). In this position, cyclohexene interacts with F154 and F63 aromatic side chains (Fig. 4C and S22†), similarly to what is observed for octane (Fig. 4B). We hypothesised that by utilising a prochiral cyclohexene, this improved positioning would lead to substantially improved stereoselectivities. By using 1-methyl-1-cyclohexene, the enantioselectivity was indeed significantly improved in the epoxide **3** formation from the wildtype (17% ee) to variant A161L (75% ee).

Variant L60A, which displayed the selective epoxidation of cyclohexene in presence of octane, showed decreased conversions relative to the wildtype in the single substrate setup with 1160 TONs (Table S5†). MD simulations performed with cyclohexene and octane independently bound in L60A variant indicate that this mutation induces an enlargement of the active site region near the Cpd I active species. Cyclohexene bound in this wider active site can explore catalytically competent poses concerning Cpd I active species (Fig. S21†). However, octane can barely explore reactive conformations towards the Cpd I due to the less tight binding and its higher flexibility in this enlarged active site (Fig. S17†). Together with the intrinsic energetically less favourable octane hydroxylation than competing cyclohexene epoxidation (see DFT calculations Fig. S13 and S14†), the latter is proposed to be responsible for the observed substrate selective oxidations.

Based on these results, we were highly interested to employ variant A161L in the epoxidation of styrene derivatives (Fig. 3C). The expected styrene oxide (**4**) formation was improved 4.5-fold relative to the wildtype to 5030 TONs. Besides this significantly improved activity, variant A161L also exhibited a shift in stereoselectivity. Whereas the wildtype exhibited the formation of the epoxide **4** in the *R*-conformation with 32% ee, variant A161L produced excess of the *S*-enantiomer with a 28% ee. Comparing variant A161L to the wildtype when using α -methyl-styrene, resulted in similar observation. A161L showed an excess in the formation of the epoxide **5** and an excess of the *S*-enantiomer (29% ee), whereas the wild type exhibited selectivities for the *R*-enantiomer formation (77% ee, (Fig. S7†).

Lastly, we assessed *cis*-methyl-styrene for its epoxidation. We were surprised to note that as products for the WT and the variant A161L the allylic hydroxylation and overoxidation to the aldehyde was observed instead of the expected epoxidation. This activity contrasts with the well-characterised *Aae*UPO with its high selectivity for *cis*-methyl-styrene epoxidation.⁴

Conclusions

In the present work, we have performed protein engineering targeting the recently characterised *Mth*UPO to address its limitations in terms of low chemo-, and regioselectivity towards aliphatic carbon hydroxylation and C=C bond epoxidation, respectively. Since no versatile assay was available to screen for these selectivities, we developed a high throughput screening allowing the quantification of seven analytes simultaneously. We used an off-the-shelf GC-MS without further modifications rendering this method feasible and accessible for many academic laboratories. As the product distinction and quantification is based on mass spectrometric abundance, this allowed the distinction of products with different masses like allylic hydroxylation vs epoxidation and substrate preference directly from the reaction product mixtures. We further expanded the system to allow the simultaneous quantification of regioisomers with identical masses by derivatisation allowing their quantification by regiospecific fragmentations during ionisation. This multiple substrate screening approach allows gaining the maximal information of an enzyme library thereby significantly decreasing the required screening amount and efforts. A unique mass (fragment) is indispensable for the MISER-GC-MS methodology, which required in this work an additional laboratory work-up to access several small products in parallel. Seven wild type UPOs were screened towards their activity and selectivity for octane, cyclohexane and cyclohexene oxidation simultaneously. The novel *Mth*UPO was selected and conducted to mutagenesis at nine selected positions resulting in a focused enzyme library of 900 transformants. Screening this relatively small library resulted in identifying three enzyme variants with divergent chemo- and regioselectivities. One variant (F154V) exhibited pronounced activity towards the 4-octanol formation, and L60A almost exclusively performed cyclohexene epoxidations. Most strikingly was the discovery of A161L variant, that revealed 38% regioselectivity towards the terminal hydroxylation of octane—an activity otherwise only once observed with UPOs.¹² Computational modelling based on DFT calculations and substrate-bound MD simulations was performed to rationalise the observed reactivity patterns. MD simulations showed that reshaping the active site due to specific mutations was responsible for modulating the preferential substrate binding poses, controlling the final chemo- and regioselectivities observed.

The presented data showed utterly new insights into UPO activities. The employed method permits vastly increased

insights into small enzyme libraries that will be extremely useful for coming efforts in UPO and general enzyme engineering and laboratory evolution.

Author contributions

A. K. and M. J. W. designed the project and the experiments for the method development of multiple substrate MISER-GC-MS. P. P. established the original *S. cerevisiae* expression system for UPOs. A. K. performed the mutagenesis and A. K. and N. H. performed the *S. cerevisiae* cultivations. The multiple substrate bioconversion, the analysis by MISER-GC-MS and the hit verification was done by A. K.; and J. S. and M. G. B. designed the computational modelling. J. S. performed the DFT calculations and MD simulations under M. G. B. supervision, and both analysed the computational data. M. J. W., M. G. B. and A. K. wrote the manuscript.

granted permission of the American Chemical Society (dated 4th May 2021) for publication within this thesis under confirmed consent of the responsible editor Prof. Claudia E. Vickers.

Within this concluding chapter the previously developed episomal UPO secretion system in the methylotrophic yeast *Pichia pastoris* has been further expanded to enable additional shuffling of promoter units. Eleven methanol-inducible promoter elements derived either from *Pichia pastoris* or the methylotrophic yeast *Hansenula polymorpha* were introduced as basic parts into the modular system. Through complementary design with the previously constructed signal peptide shuffling system, 187 unique promoter-signal peptide combinations for the secretion of a target protein can be assessed through a simple one-pot one-step cloning approach. Applying this dual shuffling system, the episomal secretion of three previously characterised UPOs could be increased. Through the introduction of three additional UPO genes, two could be produced recombinantly for the first time and the production titre of a third UPO substantially increased when compared to reports about heterologous production in *E. coli*. The dual shuffling system could further be successfully applied to identify highly suitable episomal secretion constructs for two other industrially highly relevant enzyme classes– namely a lipase and a laccase, which can serve as promising starting points for subsequent directed evolution campaigns.

Improving the Heterologous Production of Fungal Peroxygenases through an Episomal *Pichia pastoris* Promoter and Signal Peptide Shuffling System

ABSTRACT: Fungal peroxygenases (UPOs) have emerged as oxyfunctionalization catalysts of tremendous interest in recent years. However, their widespread use in the field of biocatalysis is still hampered by their challenging heterologous production, substantially limiting the panel of accessible enzymes for investigation and enzyme engineering. Building upon previous work on UPO production in yeast, we have developed a combined promoter and signal peptide shuffling system for episomal high throughput UPO production in the industrially relevant, methylotrophic yeast *Pichia pastoris*. Eleven endogenous and orthologous promoters were shuffled with a diverse set of 17 signal peptides. Three previously described UPOs were selected as first test set, leading to the identification of beneficial promoter/signal peptide combinations for protein production. We applied the system then successfully to produce two novel UPOs: *Mfe*UPO from *Myceliophthora fergusii* and *Mhi*UPO from *Myceliophthora hinnulea*. To demonstrate the feasibility of the developed system to other enzyme classes, it was applied for the industrially relevant lipase CalB and the laccase Mrl2. In total, approximately 3200 transformants of eight diverse enzymes were screened and the best promoter/signal peptide combinations studied at various cofeeding, derepression, and induction conditions. High volumetric production titers were achieved by subsequent creation of stable integration lines and harnessing orthologous promoters from *Hansenula polymorpha*. In most cases promising yields were also achieved without the addition of methanol under derepressed conditions. To foster the use of the episomal high throughput promoter/signal peptide *Pichia pastoris* system, we made all plasmids available through Addgene.

KEYWORDS: fungal peroxygenases, UPO, *Pichia pastoris*, high throughput screening, promoter shuffling, protein secretion

Fungal unspecific peroxygenases (UPOs) have gained substantial interest as versatile oxyfunctionalization biocatalysts since their initial description in 2004.¹ UPOs are solely relying on hydrogen peroxide as cosubstrate for the formation of the reactive oxyferryl (Compound I) intermediate. In contrast to the well-known cytochrome P450 enzymes, they do not rely on auxiliary electron transport proteins and expensive cofactors.^{2,3} Recent studies demonstrate impressive activities on a wide variety of structurally diverse substrates.^{4–6} Arguably the major bottleneck in the widespread use of UPOs, naturally occurring as disulfide-bridged, glycosylated, secreted enzymes, remains their challenging heterologous production.^{2,7,8} Recent work describes the production of three UPOs in *E. coli*; however, the reported recombinant yields are comparably low, and proof for the high throughput capacity of the developed prokaryotic system is lacking.^{9,10} Utilizing the eukaryotic host *Saccharomyces cerevisiae*, *Aae*UPO derived from *Agrocybe aegerita* was engineered for active secretion to a titer of 8 mg/L.¹¹ Subsequent directed evolution approaches based on this yeast-secretion variant *Aae*UPO* led

to improved variants for the synthesis of 1-naphthol and 5'-hydroxypropranolol.^{12,13} The UPO secretion variant could also be successfully produced utilizing the methylotrophic yeast *Pichia pastoris* (syn. *Komagataella phaffii*).¹⁴

P. pastoris represents an industrially highly relevant heterologous production platform due to beneficial metabolic characteristics as well as a steadily growing toolbox of valuable synthetic biology parts such as modular circuits, strong as well as tightly regulated promoters and signal peptides.^{15–17} Especially promoter elements are popular, which are derived from genes involved in the specialized methanol utilization (MUT) pathway. The most famous and commonly used MUT

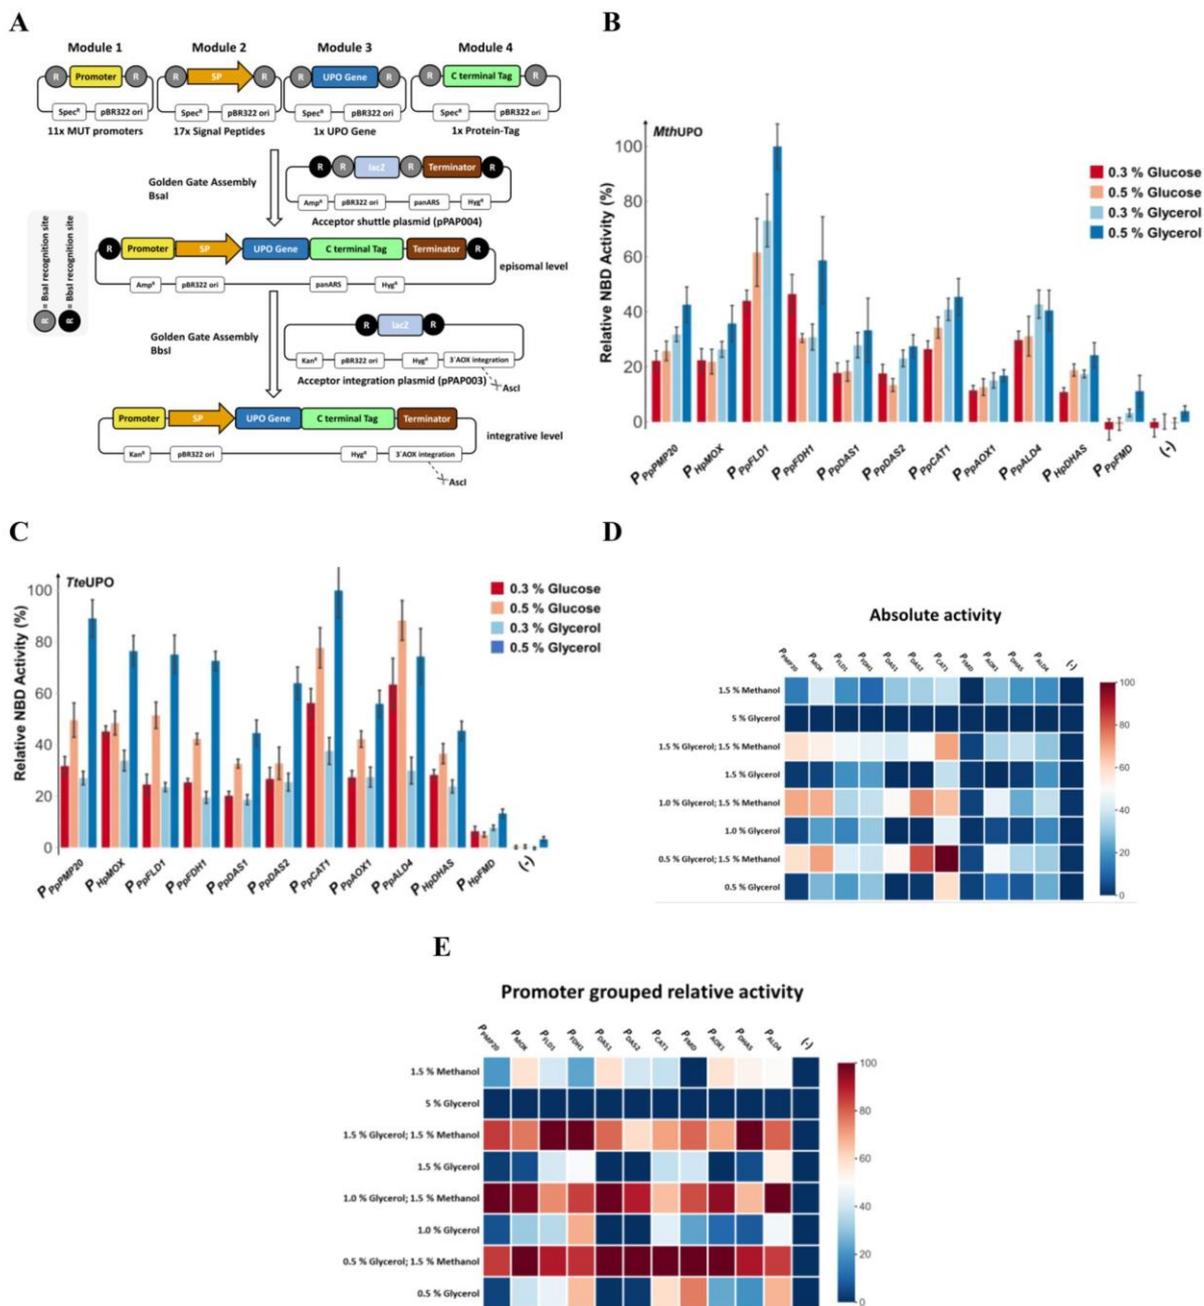

Figure 1. Design and testing of the episomal MUT expression shuffling system in *P. pastoris*. (A) Episomal tetrapartite expression units (5′ to 3′: MUT promoter–signal peptide–UPO Gene–C-terminal tag) can be assembled within an *E. coli/P. pastoris* shuttle plasmid (pPAP004) and transformed yeast clones are screened for activity. In a second Golden Gate reaction, the previously identified, suitable expression units can be transferred to another plasmid (pPAP003) for stable genomic integration, yielding strains for high yield protein production. (B) Testing of individual MUT promoter strengths using *MthUPO* as test enzyme (signal peptide: “*Sce-α*-Galactosidase”). Six biological replicates were cultivated within the MTP setup and UPO specific NBD conversion were measured in the supernatant after 72 h cultivation. (–) in every case indicates the empty plasmid control (pPAP004). The highest mean activity was set as 100% and all other means were normalized relative to this value, standard deviations are indicated. Carbon sources were used in a cofeeding system utilizing two sources, glucose or glycerol as indicated and 1.5% methanol in all cases. (C) Analogous setup to B but using *TteUPO* as test enzyme (signal peptide: “*Sce*-Invertase 2”). (D,E) Carbon source screening of *TteUPO* constructs as before (like setup C) tested under 8 different carbon source conditions utilizing methanol induced (0.5% to 1.5% glycerol plus 1.5% methanol and 1.5% methanol) and methanol-free conditions (0.5 to 5% glycerol). Cultivation, screening, and analysis as described before. (D) The overall highest measured mean activity was set to 100%. (E) The highest mean activity of every promoter was set to 100% and all other mean values normalized accordingly leading to the heatmaps as shown.

ACS Synth. Biol. XXXX, XXX, XXX–XXX

59 based promoter, AOX1, is derived from the alcohol oxidase 1
60 gene. The widespread application of these promoters is based
61 on their common tight repression and strong methanol
62 induction profile.^{18,19} Besides this sharp repression vs
63 induction profile, several MUT promoters were described in
64 recent years, enabling methanol-free derepressed gene
65 expression upon carbon source depletion. This derepressed
66 gene expression is of high interest as methanol bears drawbacks
67 as inducer in the course of large-scale fermentations as toxic
68 and flammable agent.^{19,20} Recent studies report orthogonal
69 MUT promoter elements derived from the methylotrophic
70 yeast *Hansenula polymorpha* (syn. *Ogataea angusta*) out-
71 performing endogenous, strong *P. pastoris* MUT promoters
72 for target protein production.^{21,22}

73 Despite being a heterologous host of outstanding interest,
74 the use of *P. pastoris* for high throughput enzyme engineering
75 endeavors remains rather limited to few examples.^{23–27} This is
76 likely due to a limited number of suitable autonomously
77 replicating sequences (ARS) for *P. pastoris*, which confer
78 episomal stability. For the model yeast organism *S. cerevisiae*, a
79 multitude of directed evolution examples exist utilizing well-
80 known episomal systems.^{11,28,29}

81 In this work we present a high throughput episomal
82 expression system for *P. pastoris*. The system is based on
83 principles of modular Golden Gate cloning^{30–32} and enables
84 the rapid assessment of the suitability of promoter/signal
85 peptide combinations for recombinant protein secretion.
86 Eleven orthogonal or endogenous MUT promoters can be
87 combined with 17 signal peptides for each individual gene of
88 interest, leading to 187 unique combinations. This system was
89 validated and optimized using known UPOs and further
90 enabled the first yeast production of *Dca*UPO and the
91 discovery of two new UPOs. To demonstrate versatility of
92 the system, ideal episomal combinations were additionally
93 determined for the lipase CalB and the laccase Mrl2.

94 After the screening of approximately 3200 primary trans-
95 formants in the episomal *P. pastoris* setup, the best performing
96 transcription units were genomically integrated and led to high
97 production titers within shake flask production setups.

98 ■ RESULTS AND DISCUSSION

99 **Building and Testing the Setup.** We selected 11 MUT
100 promoters: eight derived from *P. pastoris* ($P_{PpPMP20}$; P_{PpFLD1} ;
101 P_{PpFDH1} ; P_{PpDAS1} ; P_{PpDAS2} ; P_{PpCAT1} ; P_{PpAOX1} ; P_{PpALD4}) and three
102 orthologous promoters from *H. polymorpha* (P_{HpMOX} ; P_{HpDHAS} ;
103 P_{HpFMD}).^{17,19,21} All promoters were cloned as Level 0 modules
104 into pAGM9121 bearing an identical Kozak sequence
105 ($-^{10}$ ATCATACAAA⁰ATG). The design was implemented to
106 be fully compatible with the previously designed yeast
107 secretion system (Supplemental Figure S1).³³ A detailed list
108 of all promoter and signal peptide sequences and their
109 phylogenetic background is given (Supplemental Tables S2
110 to S4). Tetrapartite expression units (S' promoter–signal
111 peptide–gene–C-terminal tag $3'$) are assembled in a one-pot,
112 one-step Golden Gate reaction within the episomal yeast
113 expression plasmid pPAP004, which can be propagated in
114 *E. coli* as well as *P. pastoris* (Figure 1 A). Identified beneficial
115 promoter-signal peptide combinations can be swapped as
116 complete transcription unit into an integrative plasmid
117 (pPAP003) in the course of a second Golden Gate reaction
118 leading to stable strains for high yield and antibiotic-free
119 protein production. The overall experimental workflow is

depicted in Supplemental Figure S2. As a first test object, the
recently described enzyme *Mth*UPO was chosen.

In the initial approach, all MUT promoter constructs were
built in combination with the previously identified suitable
signal peptide “*Sce- α* -Galactosidase” for the secretion of
*Mth*UPO derived from *Myceliophthora thermophila*.³³ This
approach led to 11 defined constructs. *P. pastoris* cells were
cultivated for 72 h in 96 well plates using a cofeeding strategy
of the primary carbon source glucose or glycerol (0.3 or 0.5%
(w/v)) and the inducing carbon source (1.5% (v/v)
methanol). Except for P_{HpFMD} , all promoters led to a
distinguishable activity using the UPO specific NBD Assay³⁴
and when compared to the negative control (pPAP004) under
all tested cofeeding conditions (Figure 1 B). In general, P_{PpFLD1}
appeared to be the most suitable promoter for *Mth*UPO
production, and the cofeeding conditions using 0.5% glycerol
led to the highest average activity of all promoters.

As a second test, the previously described enzyme *Tte*UPO
from *Thielavia terrestris* was selected (Figure 1 C). *Tte*UPO
was combined with all respective promoters following the same
principles as before but combined with the signal peptide “*Sce*-
Invertase 2”.³³ General observations were similar to the
screening of *Mth*UPO, but identifying P_{PpCAT1} as most suitable
promoter within this setup and obtaining clear UPO activities
for all promoters including P_{HpFMD} .

Since some of the included promoters were previously
described to gain activity under conditions of primary carbon
source depletion (derepression) we further wanted to test the
UPO production behavior of the 11 MUT promoter under
varying derepressive/inductive carbon sources.^{18,19,21,35} We
chose various cofeeding (0.5 to 1.5% glycerol + 1.5%
methanol), derepressive (0.5 to 1.5% glycerol), excess (5%
glycerol), and solely methanol (1.5%) conditions. The negative
control (pPAP004) and all MUT samples under excess
glycerol conditions did not exhibit any UPO activity (Figure
1 D and E). This tight repression demonstrated that promoter
activity and UPO production are solely based on methanol
induction or carbon source depletion based derepression. In all
cases, the highest UPO production rates were obtained
employing a cofeeding strategy using 0.5% (5 promoters) or
1 to 1.5% glycerol (3 promoters each). Interestingly, using
methanol as sole carbon source and inducing agent, resulted in
a reduced cell density and decreased UPO activity (approx-
imately 20–60% of maximal activity). This observation
highlights the appeal of the cofeeding setup for optimal
protein production.

On the basis of the observed production patterns within this
setup, the MUT promoters can be grouped in solely methanol
inducible ($P_{PpPMP20}$; P_{PpDAS1} ; P_{PpDAS2}), slightly derepressed
(P_{HpMOX} ; P_{HpDHAS} ; P_{PpAOX1}), medium (P_{PpFLD1}), and strongly
derepressed (P_{PpFDH1} ; P_{PpCAT1} ; P_{PpALD4} ; P_{HpFMD}).

Time course investigations were performed from 20 to 100 h
after inoculation of *Tte*UPO constructs utilizing six dere-
pressed promoters (Supplemental Figure S3). In general, it
could be observed that UPO activity primarily accumulates in
the supernatant in the interval between 30 and 50 h,
correlating with reaching the maximal cell density within the
wells. After that, the UPO activity slightly increased until the
end point (100 h) within most setups. Interestingly, testing
range spanning derepressed conditions (0.5; 1.0 or 1.5%
glycerol) resulted in no substantial differences in the activity
pattern of any promoter. We did not obtain any evidence for
an occurring lag-phase of derepressed UPO production when

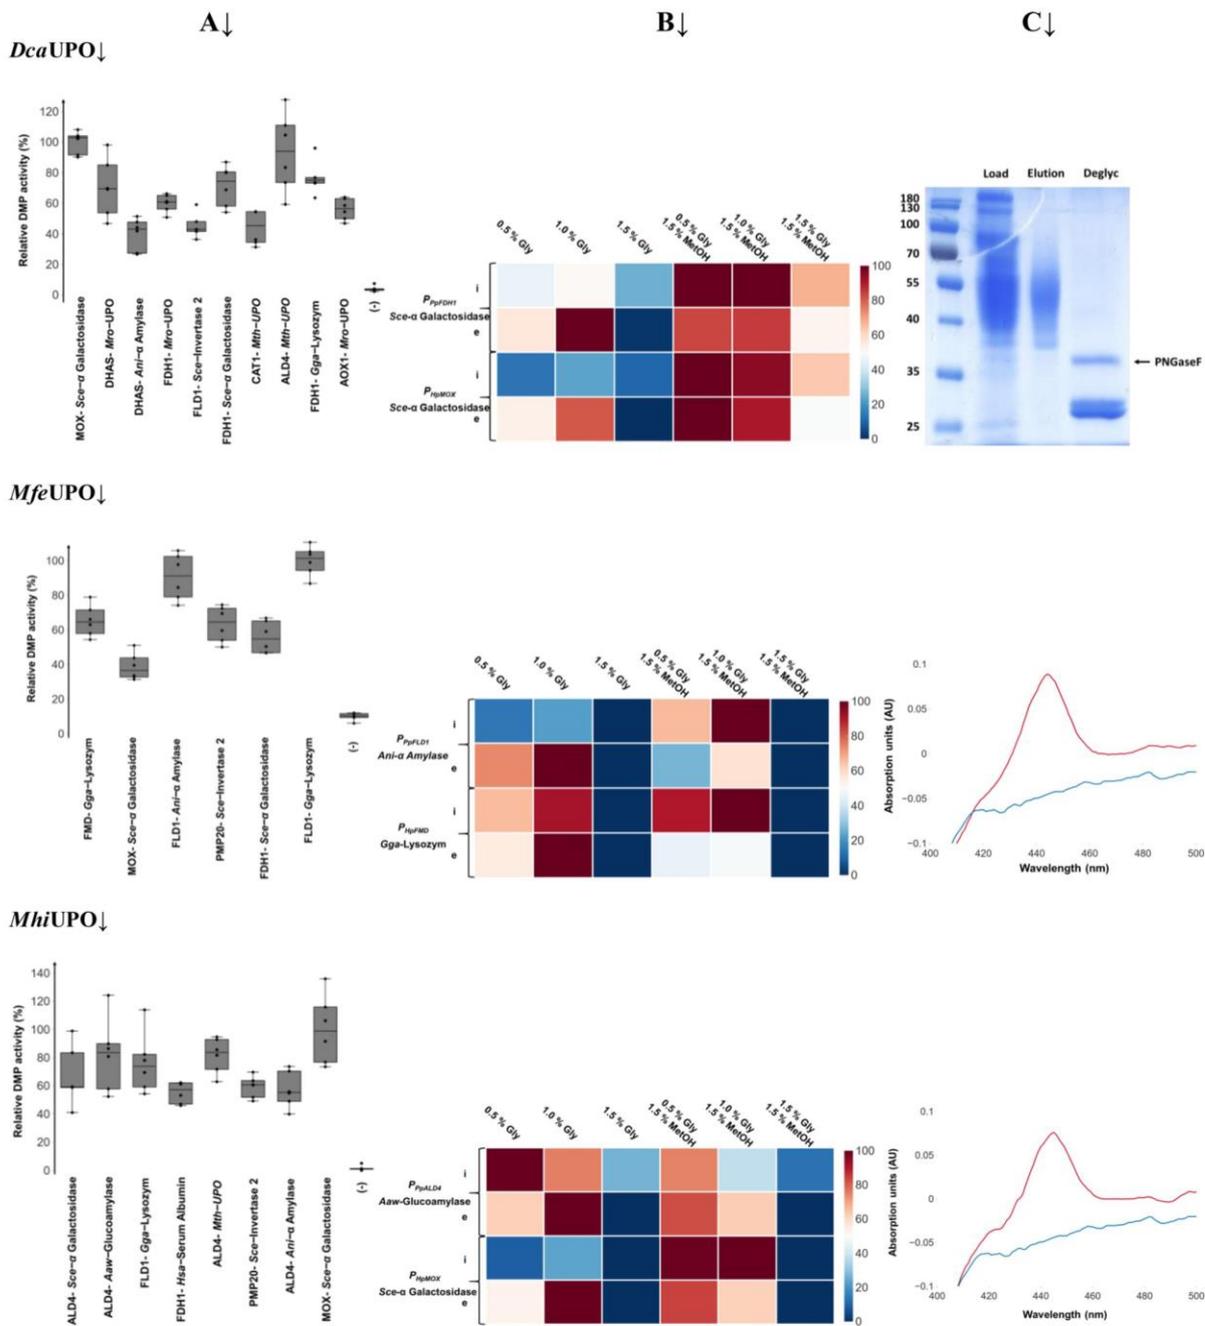

Figure 3. Testing the heterologous production of novel UPOs. Two previous UPOs (*Mhi*UPO and *Mfe*UPO) and a recently described UPO (*Dca*UPO) were subjected to one-pot, one-step promoter/signal peptide shuffling (187 possible unique combinations). (A) Relative activity of nonredundant constructs among the most active 15 clones. Six biological replicates were cultivated within the MTP setup and UPO-specific DMP conversion measured in the supernatant after 72 h cultivation. (–) in every case indicates the empty plasmid control (pPAP004). The highest mean activity was set as 100% and all other data points normalized relative to this mean value. (B) Comparison of top two episomal (e) and integrative constructs (i) regarding UPO activity utilizing differing carbon source production conditions (screening conditions as described in A). The highest mean activity of every group was set to 100% and all values normalized accordingly. Primary data are displayed in Supplemental Figure S12. (C) One-step HIC-based purification of recombinant *Dca*UPO. Load (50 mL sample after ultrafiltration), pooled elution (Elution), and elution fraction after enzymatic N-deglycosylation (PNGaseF treatment; Deglyc) were analyzed by SDS-PAGE (12%). *Mfe*UPO and *Mhi*UPO (red) were analyzed after ultrafiltration by differential CO spectra in comparison with the integrative negative control (pPAP003; blue).

183 using higher glycerol concentrations (1.5%) over low
184 concentrations (0.5%).

185 Combining Signal Peptide and Promoter Shuffling.

186 In previous studies using two promoters and various signal
187 peptides, we observed rather surprising effects of certain
188 combinations on the UPO yield.³³ The classical model of
189 selecting a strong promoter and a suitable signal peptide for
190 secretion was valid in many cases. Still, individual results
191 pointed toward pronounced synergistic effects of chosen
192 promoter/signal peptide combinations on the UPO activity
193 rather than selecting a strong promoter to drive target gene
194 expression. We built and tested 18 *Tte*UPO constructs to
195 further investigate this preliminary observation. Three
196 previously as suitable identified promoters (P_{HpmOX} ; P_{PpALD4} ;
197 P_{PpCAT1}) and six suitable signal peptides were employed
198 (Supplemental Figure S4). In three cases with the signal
199 peptides “*Sce*-Prepro”, “*Sce*-Invertase 2”, and “*Sce*-Killer
200 Protein” an expected promoter-based pattern of UPO activity
201 was observed: $P_{PpCAT1} > P_{HpmOX} \geq P_{PpALD4}$. In two cases (“*Mro*-
202 UPO” and “*Kma*-Inulinase”), the obtained UPO activity of the
203 P_{PpCAT1} construct was approximately doubled in comparison to
204 the other promoters. Even more surprising, this observation
205 was inverted in one case (“*Hsa*-Serum Albumin”) toward
206 P_{HpmOX} outperforming the other two promoters by 2-fold.
207 These results further strengthen a more synergistic hypothesis
208 of episomal protein secretion in *P. pastoris*, rather than just
209 taking promoter strength and signal peptide suitability into
210 consideration as isolated factors.

211 On the basis of this synergism hypothesis, we performed all
212 subsequent enzyme screenings as combined promoter-signal
213 peptide shuffling approaches with 11 MUT promoters and 17
214 signal peptides leading to 187 unique combinations. The
215 resulting libraries were transformed into *P. pastoris* and 370 to
216 378 transformants of each library screened for UPO specific
217 NBD activity using a cofeeding of 0.5% glycerol and 1.5%
218 methanol, which was previously identified as most suitable
219 carbon source for most promoters (Figure 1 E). Initial
220 screening of the libraries of *Tte*UPO, *Mth*UPO, and
221 *Aae*UPO*^{11,14} revealed differing patterns. *Tte*UPO and
222 *Mth*UPO exhibited a high promiscuity regarding functional
223 promoter/signal peptide combinations. 66% (*Tte*UPO) and
224 56% (*Mth*UPO) of all transformants exhibited UPO activity
225 (Supplemental Figure S5 and S6). For *Aae*UPO*, however,
226 just a small fraction of 7% of the transformants were active
227 (Supplemental Figure S7). These observations are consistent
228 with previous findings performing a signal peptide shuffling
229 approach with these enzymes.³³ So far only one long-type
230 UPO variant has been reported to be successfully secreted in
231 yeast,^{11,14} whereas four wild type short-type UPOs were
232 recently reported to be produced in yeast.³³

233 Among the top 15 most active hits of each enzyme, a vast
234 diversity of shuffled promoters (*Tte*UPO: 5; *Mth*UPO: 6;
235 *Aae*UPO*: 7) and signal peptides parts (*Tte*UPO: 8; *Mth*UPO:
236 8; *Aae*UPO*: 2) could be observed (Figure 2 A). The low
237 diversity of signal peptides for *Aae*UPO* is in good agreement
238 with previous findings that suggested low promiscuity of this
239 enzyme toward the signal peptide panel.³³

240 Subsequent carbon source dependent activity screening was
241 performed of the top two performing episomal (abbreviated
242 with (e) and their integrative counterparts (i)) (Figure 2 B).
243 These carbon source variations revealed a diverse dynamic of
244 UPO production under derepressed and induced conditions.
245 The *H. polymorpha* derived promoter P_{HpfEMD} proved to be the

best performing promoter in case of all enzymes. The highest 246
NBD activity under episomal production however varied for 247
every UPO. The highest levels were obtained under cofeeding 248
conditions for *Tte*UPO (1.0% glycerol; 1.5% methanol) and 249
*Mth*UPO (0.5% glycerol; 1.5% methanol) and for *Aae*UPO* 250
even under methanol-free conditions with 1.0% glycerol. 251
Therefore, a “sweet spot” for every episomal construct can 252
be found by carbon source screening. The ideal carbon source 253
condition can then be further exploited as a standard condition 254
to obtain maximal enzyme yields easing high throughput 255
directed evolution endeavors. Utilizing one step TwinStrep- 256
based affinity purification, all UPOs were obtained in high 257
purity and analyzed for their extent of glycosylation and 258
molecular weight by SDS PAGE, obtaining apparent molecular 259
weights of 27 kDa (*Tte*UPO), 35 kDa (*Mth*UPO) and 45 kDa 260
(*Aae*UPO*, Figure 2 C). Interestingly, when producing 261
*Tte*UPO before in the identical *P. pastoris* strain but utilizing 262
a different signal peptide (“*Sce*-Prepro”), we obtained a 263
deglycosylated apparent MW of 35 kDa.³³ This observation 264
and the calculated molecular weight based on the enzyme’s 265
primary sequence of 32 kDa suggests an occurring divergent 266
cleavage of an N-terminal part of the mature enzyme. 267

Introducing Novel UPOs into the Modular System.

268 Taking the recently characterized *Mth*UPO as search query, we 269
retrieved the sequences of two close homologues from a recent 270
patent.³⁶ The UPO from *Myceliophthora fergusii* (*Mfe*UPO) 271
and from *Myceliophthora hinnulea* (*Mhi*UPO) share a high 272
sequence identity of 91% and 96% toward *Mth*UPO. As the 273
third UPO, we selected the *Dca*UPO derived from *Daldinia* 274
caldariorum, recently produced in *E. coli*.¹⁰ *Dca*UPO has a 275
moderate sequence identity of 53% and 52% toward *Mth*UPO 276
and *Tte*UPO, respectively. The three new enzymes were 277
subjected to the promoter/signal peptide shuffling approach. 278
The resulting libraries were screened for UPO-specific activity 279
using colorimetric screening assays with NBD or DMP as 280
substrate. Primary screening landscapes revealed comparable 281
proportions of active transformants for *Dca*UPO (26%), 282
*Mfe*UPO (24%), and *Mhi*UPO (31%, Supplemental Figures 283
S9–S11). These proportions point toward a less pronounced 284
promoter/signal peptide promiscuity than *Mth*UPO (56%) 285
and *Tte*UPO (66%), but higher than *Aae*UPO* (7%). Since 286
the signal intensity of the NBD assay in case of the enzymes 287
appeared to be rather low, further screenings of the three novel 288
UPOs were conducted employing the more sensitive DMP 289
assay.¹² 290

291 The top 15 hits exhibited a redundant pattern, due to the 291
performed oversampling, limiting the number of unique 292
constructs to a range between 6 (*Mfe*UPO) and 10 (*Dca*UPO), 293
Figure 3 A). Nevertheless, as before a diverse panel of 294
promoters (*Dca*UPO: 7; *Mfe*UPO: 5; *Mhi*UPO: 5) and signal 295
peptides (*Dca*UPO: 6; *Mfe*UPO: 4; *Mhi*UPO: 7) was 296
observed. Carbon source activity screening identified two 297
H. polymorpha promoters occurring within the best performing 298
constructs: P_{HpfEMD} (*Mfe*UPO) and P_{HpmOX} (*Mhi*UPO, 299
*Dca*UPO, Figure 3 B). As shown before for all enzymes, a 300
specific “sweet spot” of maximal activity within the episomal 301
system was identified, while in case of *Dca*UPO cofeeding 302
(0.5% glycerol; 1.5% methanol) led to maximal activity, 303
*Mfe*UPO and *Mhi*UPO activity reached its maximum under 304
derepressed condition with 1% glycerol. 305

306 Purification of the three UPOs proved to be challenging. 306
They could not be purified by means of affinity based 307
TwinStrep purification. This is most likely caused by masking 308

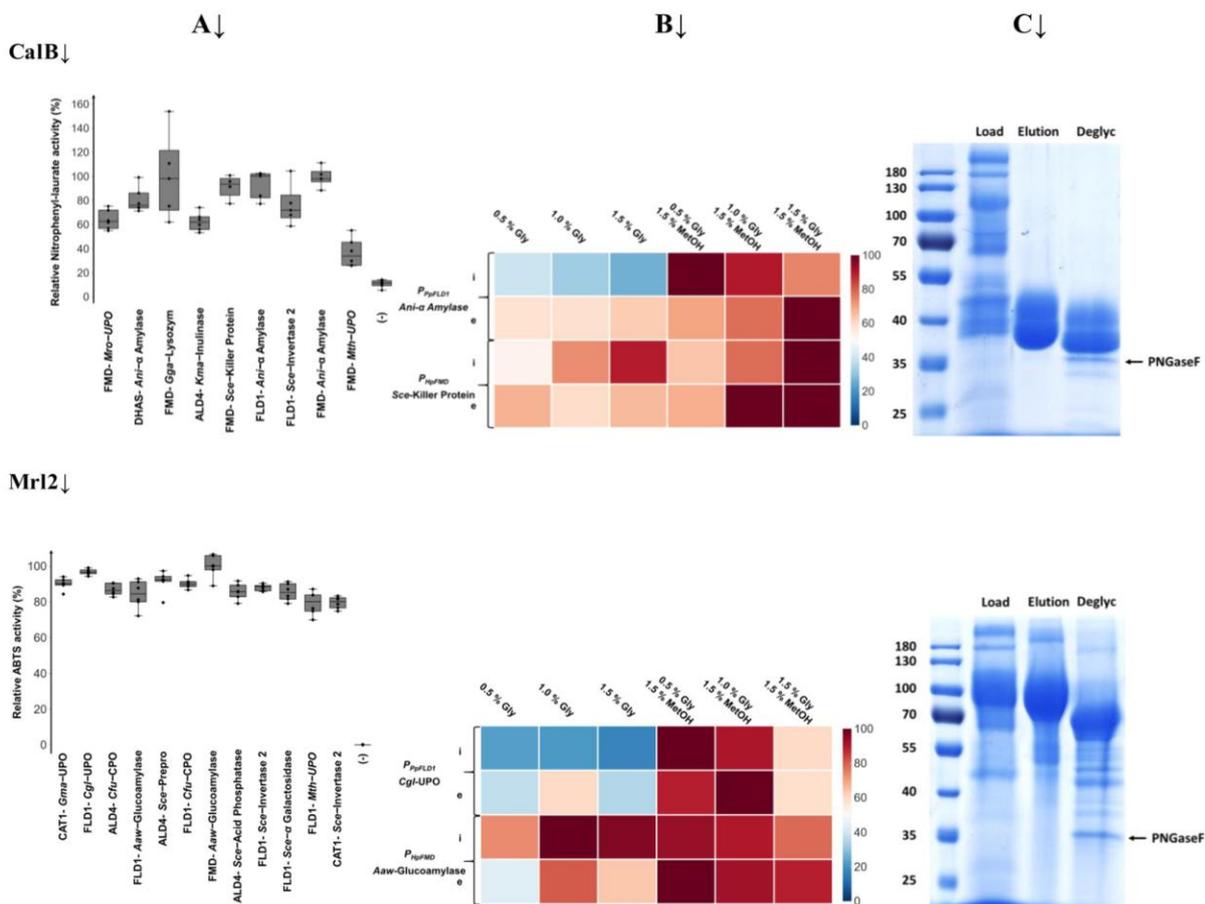

Figure 4. Expanding the dual shuffling system to other enzyme classes. Lipase CalB and laccase Mrl2 were subjected to one-pot, one-step promoter/signal peptide shuffling (187 possible unique combinations). (A) Relative activity of nonredundant constructs among the most active 15 clones. Six biological replicates were cultivated within the MTP setup and lipase specific (4-Nitrophenyl laurate) and laccase specific (ABTS) conversion measured in the supernatant after 72 h cultivation. (–) in every case indicates the empty plasmid control (pPAP004). The highest mean activity was set to 100% and all other data points were normalized relative to this mean value. (B) Comparison of top two episomal (e) and integrative constructs (i) regarding lipase (4-Nitrophenyl laurate) or laccase (ABTS) activity utilizing differing carbon source production conditions (screening conditions as described in A). The highest mean activity of every group was set to 100% and all values normalized accordingly. Primary data are displayed in Supplemental Figure S21. (C) One step TwinStrep-based purification of recombinant enzymes. Load (50 mL sample after ultrafiltration), pooled elution (Elution), and elution fraction after enzymatic N-deglycosylation (PNGaseF treatment; Deglyc) were analyzed by SDS-PAGE (12%).

309 of the C-terminal TwinStrep tag due to pronounced
 310 glycosylation or might point toward proteolytic cleavage of
 311 the tag. Using classical purification techniques like ion
 312 exchange (IEX) and hydrophobic interaction chromatography
 313 (HIC), the UPOs could be captured, but specific elution was
 314 not achieved. UPO activity was rather spread over all elution
 315 fractions (salt gradient) pointing toward extensive glycosyla-
 316 tion. This heavy glycosylation leads to a very heterogeneous
 317 enzyme pool with divergent physicochemical behavior, which
 318 are underlying principles of IEX and HI chromatography.
 319 Using OctylSephacrose as HIC material, we obtained a tightly
 320 bound, pure fraction of *Dca*UPO by elution with ethylene
 321 glycol. SDS PAGE analysis (Figure 1 C and Supplemental
 322 Figure S13) revealed high purity as well as an extensive
 323 glycosylation with an apparent molecular weight of 40 to 55
 324 kDa, which was reduced to approximately 27 kDa after
 325 deglycosylation. This apparent molecular weight reduction is in

good agreement with the calculated molecular weight of
 326 *Dca*UPO. In the case of *Mfe*UPO and *Mhi*UPO, purification
 327 was not successful, but precise heme CO differential spectra
 328 were obtained compared with the integrative negative control
 329 pPAP003 (Figure 3 C and Supplemental Figure S17).

Suitability for Directed Evolution Approaches. To
 331 access the suitability of the designed system for directed
 332 evolution approaches, various parameters were tested. First, we
 333 investigated the obtained cell density after 96 well plate
 334 cultivation, which is in combination with the obtained readout
 335 (fluorescence/activity) a normalization commonly used.¹⁵
 336 Testing the *Tte*UPO promoter library (Figure 1 C), as well
 337 as one episomal and genomically integrated P_{HPFMD} construct
 338 under all employed carbon source screening conditions no
 339 apparent difference in cell density were measured, also when
 340 compared to pPAP004 and the X-33 wild type strain
 341 (Supplemental Figure S13). These measurements are con-
 342

Table 1. Volumetric Protein Yields of Recombinant Enzymes

enzyme	promoter	signal peptide	derepressed ^a (mg/L)	induced ^b (mg/L)	literature yield ^{source} (mg/L)
<i>Tte</i> UPO	<i>P</i> _{HpFMD}	Ani- α -Amylase	4.8	21.9	14 ³³
<i>Mth</i> UPO	<i>P</i> _{HpFMD}	Gga-Lysozym	3.7	22.4	24 ³³
<i>Aae</i> UPO*	<i>P</i> _{HpFMD}	Gma-UPO	6.0	12.6	8 ¹⁴
<i>Dca</i> UPO	<i>P</i> _{HpMOX}	Sc α -Galactosidase	n.d. ^c	16.3	2.8 ¹⁰
<i>Mhi</i> UPO	<i>P</i> _{HpMOX}	Sc α -Galactosidase	0.1	5.7	/
<i>Mfe</i> UPO	<i>P</i> _{HpFMD}	Gga-Lysozym	3.2	6.5	/
CalB	<i>P</i> _{HpFMD}	Sc α -Killer Protein	15.6	21.6	44.5 ³⁸
Mrl2	<i>P</i> _{HpFMD}	Aaw-Glucoamylase	8.0	30.9	10.6 ³⁷

^aMain culture inoculated at OD_{600nm} = 0.3 and 1.0% (w/v) glycerol as sole carbon source (72 h cultivation time) ^bMain culture inoculated at OD_{600nm} = 0.3 and 0.4% (w/v) glycerol; addition of 1% (v/v) methanol after 24 and 48 h (72 h cultivation time) ^cn.d.: no detectable UPO production.

343 sistent with optical inspections of the screening plates;
344 therefore, optical density normalization was not performed in
345 further screenings.

346 Clonal variations of 96 well plate UPO production setups
347 were assessed for *Aae*UPO*, *Mth*UPO, *Tte*UPO, *Dca*UPO and
348 *Mhi*UPO by means of DMP activity measurements leading to
349 standard deviations of 18%, 23%, 22%, 19% and 23%,
350 respectively (Supplemental Figure S15). These deviations
351 render the system suitable, but are comparably high when
352 related to the production and screening of *Aae*UPO* in an
353 analogous *S. cerevisiae* system, stating 12% deviation.¹² This
354 analysis indicates further room for improvements in the
355 interclonal variation as it is an important factor for directed
356 evolution endeavors.^{11,12}

357 In general, identified screening hits were streaked out
358 (Supplemental Figure S2) and subsequently utilized for activity
359 rescreening and plasmid recovery for sequencing. When testing
360 streak-outs and retransformations of the obtained plasmids, we
361 observed surprising effects on the UPO activity in subsequent
362 screenings (Supplemental Figure S14). While the activity was
363 highly consistent throughout the screenings, in nearly all cases
364 a pronounced higher activity (up to 3-fold) could be observed
365 when inoculating cells stemming from a streak-out. There
366 seems to be a beneficial effect of constant Hygromycin B
367 selection on plates (months) on the activity—we are currently
368 unable to explain this effect, but it is a subject of current
369 investigations.

370 To probe the feasibility of the developed system for directed
371 evolution endeavors we constructed five random mutagenesis
372 libraries by means of error prone PCR using *Tte*UPO as gene
373 template and varying manganese chloride concentrations.
374 Subsequent DMP activity screenings (Supplemental Figure
375 S16 and Supplemental Table S7) revealed the expected activity
376 landscapes' strong correlation with the applied mutational load
377 (MnCl₂ concentration). We identified variants with an up to 3-
378 fold improved activity (Supplemental Table S7) relative to the
379 wild type.

380 **Expanding the System to Other Enzyme Classes.** After
381 successfully applying the episomal system for six UPOs we
382 wanted to further expand the system toward other enzymes
383 with a general challenging expression. We chose the widely
384 used lipase B from *Candida antarctica* (CalB) and a laccase
385 derived from the basidiomycete *Moniliophthora roreri*
386 (Mrl2).³⁷ Both enzymes were subjected to promoter/signal
387 peptide shuffling. Primary screenings were conducted using
388 well-established colorimetric assays: 4-Nitrophenyl laurate for
389 CalB and ABTS for Mrl2. The screening landscaping revealed
390 medium to high promiscuity for CalB (Supplemental Figure

S19; 44%) and the overall highest rate of active transformants 391
in the case of Mrl2 (70%). Regarding Mrl2 (Supplemental 392
Figure S20), we observed a pyramid-like shape of the activity 393
landscape when ranking the clones based on activity. This 394
shape differed substantially from the negative-exponential 395
(very few clones with high activity, many medium-high activity 396
clones) shaped landscapes for the other seven enzymes. 397
Assessing the 15 most active transformants revealed again a 398
grand diversity of occurring promoters (CalB: 4; Mrl2: 4) and 399
signal peptides (CalB: 7; Mrl2: 9, Figure 4 A). Subsequent 400
carbon source activity profiling of the top two constructs 401
(Figure 4 C) confirmed *P*_{HpFMD} as the most suitable promoter. 402
With this promoter, the highest lipase/laccase activities were 403
reached within the episomal system when a cofeeding was 404
applied: CalB with 1.0% glycerol and for Mrl2 with 0.5% 405
glycerol. 406

Contrary to the difficult purification of the novel UPOs, 407
CalB and Mrl2 were purified successfully employing TwinStrep 408
affinity chromatography (Figure 4 C). The obtained apparent 409
molecular weights for the glycosylated (CalB: 40 kDa; Mrl2: 410
100 kDa) and deglycosylated form after PNGaseF treatment 411
(CalB: 38 kDa; Mrl2: 70 kDa) are in good agreement with 412
reported data.^{37,38} 413

Volumetric Production Yields. Besides the primary focus 414
on the development of a modular episomal system, we also 415
implemented an integrative plasmid (pPAP003; Figure 1 A) as 416
second layer of the system. The integrative plasmid enables the 417
rapid construction of stable strains for large scale, antibiotic- 418
free protein production. Selecting the best performing, 419
episomal constructs of all eight previous enzymes, we 420
performed genome integration and subsequent shake flask 421
cultivations in a 1-L format. All enzymes were cultivated and 422
produced without any further production optimization for 72 h 423
(25 °C) under derepressed (1% glycerol as sole carbon source) 424
and induced conditions (start on 0.4% glycerol; 1% methanol 425
spikes after 24 and 48 h). The volumetric yields of all enzymes 426
under both conditions are displayed in Table 1. Especially 427
when using *P*_{HpFMD}, already under derepressed conditions, 428
moderate (*Mth*UPO: 17%) to high yields (CalB: 72%) were 429
obtained compared to the maximum yields with methanol 430
induction. The promoter *P*_{HpMOX} proved to be relatively 431
inactive under the tested derepression conditions, leading to 432
no (*Dca*UPO) or marginal (*Mhi*UPO) protein production. 433
The novel enzymes *Mfe*UPO and *Mhi*UPO were produced 434
with a titer of 6.5 and 5.7 mg/L respectively. We were able to 435
surpass previously reported heterologous yields of *Tte*UPO 436
(+56%) and *Aae*UPO* (+58%).^{11,33} An even more pro- 437
nounced increase was achieved for *Dca*UPO with a 482% 438

439 improvement relative to the previous reports on production in
440 *E. coli*.¹⁰ Heterologous production of *Mth*UPO was not
441 improved further but was achieved on a similar high level
442 (22.4 mg/L).³³ The volumetric yield of the laccase *Mrl2* was
443 increased by 191% reaching the overall highest volumetric
444 yield of 30.9 mg/L observed in the whole test setup. Solely the
445 production level of *CalB* could not compete with previously
446 published work.³⁸

447 **Expanding the System to *H. polymorpha*.** In the first
448 report of the utilized ARS sequence (panARS), the authors
449 also describe episomal stability in the yeast *H. polymorpha*.³⁹
450 *H. polymorpha* is, analogous to *P. pastoris*, a methylophilic
451 yeast with outstanding interest in industrial biotechnology.⁴⁰
452 We were intrigued if our constructed episomal plasmid also
453 functions in *H. polymorpha*, conferring episomal stability and
454 enabling target protein production. We transformed *H. poly-*
455 *morpha* with the *Tte*UPO promoter library (Figure 1 C) and
456 the best performing constructs of all eight enzymes. All
457 constructs contained either the promoter P_{HpfMD} or P_{HpmOX}
458 which are endogenous to *H. polymorpha*. We succeeded in
459 transforming *H. polymorpha* and 96 well cultivation under
460 comparable conditions as before with *P. pastoris*. Transformed
461 episomal plasmids could be recovered and retransformed into
462 *E. coli* and verified by sequencing, completing the standard
463 episomal workflow of *P. pastoris*. Unfortunately, the protein
464 production of the eight enzymes was not successful. No UPO/
465 lipase/laccase activity was detected. These results point toward
466 an incompatibility of the expression cassette, most likely
467 caused by the utilized terminator (GAP terminator, *P. pastoris*)
468 which might not be functional in *H. polymorpha*. The other
469 expression unit parts (promoter, signal peptides, genes, and
470 protein-tag) should be functional, *per se*.

471 In the present study, we have developed an episomal
472 *P. pastoris* expression system for combining strong methanol-
473 inducible promoters derived from *P. pastoris* and *H. polymorpha*
474 and a diverse signal peptide panel for target protein secretion.
475 Modular Golden Gate cloning enables the rapid, effective
476 construction of highly diverse promoter/signal peptide libraries
477 with up to 187 unique combinations in a one-pot, one-step
478 manner. This approach complements valuable existing systems,
479 which provide useful Golden Gate parts and circuits for *Pichia*
480 *pastoris*.^{15,17} Our focus was on building a high-throughput
481 system, relying on reproducible episomal expression, high-
482 transformation efficiencies, and using biocatalysts of high
483 relevance and challenging production as test set. We expect
484 that this research further promotes the application of *P. pastoris*
485 as host in directed evolution approaches, enabling the tailoring
486 of diverse biocatalysts while offering the possibility of effective
487 post-translational modifications.

488 We solely relied on cultivation and screening in 96 well
489 plates to demonstrate the system's high throughput potential
490 and screened approximately 3200 primary transformants of
491 eight diverse enzymes. Well-performing episomal constructs
492 were identified for all enzymes, and enzyme activities were
493 increased further by subsequent carbon source screening.

494 The screenings revealed significant differences in activity
495 distribution even when using the identical promoter. This
496 concludes that the construct cannot be assessed solely based
497 on its promoter expression strength (weak, medium, strong)
498 and regulation pattern. Secretion is substantially depending on
499 the signal peptide/gene construct and its combination with a
500 respective promoter. This insight points toward potential
501 regulatory mechanisms during translation, protein folding, and

glycosylation. A delicate balance, as high production rates of 502
heterologous proteins can also overwhelm *P. pastoris*' cellular 503
machinery and trigger protein degradation by unfolded protein 504
response.⁴¹ Recent reports also suggest the occurrence of high 505
amounts of retained nonsecreted intracellular protein.¹⁵ 506
Therefore, our system can provide a good starting point by 507
supplying a diverse range of expression strength and signal 508
peptides. Our strategy enables the rapid identification of 509
constructs balancing high activity and high functionality. Based 510
on the primary screen we could observe high (*Mrl2*: 70%; 511
*Tte*UPO: 66%; *Mth*UPO: 56%), medium (*CalB*: 44%; 512
*Mhi*UPO: 31% *Dca*UPO: 26%; *Mfe*UPO: 24%) and low 513
(*Aae*UPO*: 7%) degrees of promiscuity toward occurring 514
promoter/signal peptide combinations. 515

Our primary motivation was to develop a system to foster 516
the discovery and subsequent engineering of known and novel 517
UPOs, which are biocatalyst of outstanding interest but are 518
also infamous for their challenging heterologous produc- 519
tion.^{2,7,8} We were able to optimize the episomal (3 of 3) and 520
integrative production (2 of 3) of three known UPOs 521
(*Mth*UPO, *Tte*UPO, *Aae*UPO*).

We successfully produced the new enzymes *Mhi*UPO and 523
*Mfe*UPO for the first time. Also, the first production of 524
*Dca*UPO in yeast was achieved, increasing the obtained yield of 525
recombinant enzyme substantially. The overall volumetric 526
yields of UPO production proved to be high, ranging from 5.7 527
to 22.4 mg/L. 528

The designed two-layer system of compatible episomal and 529
integrative plasmids enables the performance of the complete 530
enzyme engineering workflow in *P. pastoris*. Following the 531
identification of a suitable promoter-signal peptide combina- 532
tion and carbon source screening for obtaining maximal 533
activity, the enzyme of choice can be rapidly evolved within the 534
episomal system and interesting, final variants directly 535
transferred to the integrative construct for subsequent high 536
yield antibiotic-free protein production and characterization. 537
As a simple proof of concept study for the use in directed 538
evolution approaches, we constructed five error prone PCR 539
randomization libraries of *Tte*UPO, leading to the identi- 540
fication of *Tte*UPO variants with an up to 3-fold increased 541
activity (Supplemental Figure S16). 542

Thereby we are bridging a gap in previous UPO engineering 543
as well as directed evolution approaches in *P. pastoris* in 544
general previously caused by the lack of suitable episomal 545
plasmids for high efficiency transformation and reproducible 546
expression. Regarding UPOs, this limitation was previously 547
overcome by a dual host approach, evolving the UPO in an 548
episomal *S. cerevisiae* system and subsequently transferring the 549
evolved variant for high yield protein production to 550
P. pastoris.¹⁴ Nevertheless the obtained activity variation of 551
approximately 20% within a 96 well plate is comparatively high 552
in regard to previous results obtained from an analogous 553
S. cerevisiae setup, stating 12% interclonal variation.¹² This 554
observation illustrates room for further improvements of the 555
episomal *Pichia pastoris* system. 556

Analysis of the distribution of respective promoter and signal 557
peptide modules among all sequenced nonredundant episomal 558
top constructs (8 enzymes; 80 samples) provided several 559
interesting insights (Supplemental Table S6). Signal peptide 560
analysis revealed a broad distribution. The most frequently 561
occurring signal peptides were "*Sce*- α -Galactosidase" and "*Gga*- 562
Lysozym" with 12.5% as well as "*Mro*-UPO" and "*Gma*-UPO" 563
with 11.3%. Surprisingly especially signal peptides derived from 564

565 UPOs (6 out of 17 in total; 33% occurrence) proved to be
566 highly valuable to target protein secretion in *P. pastoris*—also
567 in case of the unrelated enzymes CalB and Mrl2. The α -factor
568 leader “Sce-Prepro” is derived from *S. cerevisiae* and utilized as
569 standard signal peptide for target protein secretion in yeast and
570 included in nearly all commercial secretary *P. pastoris* plasmids.
571 However, it was only identified in 3.8% of our top hits. This
572 further emphasizes the appeal of a one-pot, one-step signal
573 peptide shuffling approach as it allows the probing of a diverse
574 set of signal peptides for rapid secretion testing.

575 Besides the signal peptides, substantial new insights were
576 gained into endogenous and orthologous promoters. Widely
577 used promoters within integrative plasmids (P_{ppDAS1} ; P_{ppDAS2} ;
578 P_{ppAOX1}) exhibit strong repression in the presence of glucose
579 and glycerol and strong induction profiles upon methanol
580 addition. P_{ppAOX1} thereby is the most widespread promoter and
581 is licensed in most commercial plasmid systems.^{19,42} In our
582 setup, these three promoters turned out to be the least
583 occurring promoter among the top hits (P_{ppDAS1} ; P_{ppDAS2} : 1.3%;
584 P_{ppAOX1} : 2.5%). We assume that these strongly regulated/
585 induced promoters might be less suitable for the use in
586 episomal systems based on their expression dynamics and
587 strength. The most suitable promoters were P_{ppFLD1} (23.8%),
588 P_{HpFMD} (16.3%), and P_{ppALD4} (15%). In general, we observed
589 that the derepression behavior is strongly correlating with the
590 suitability and occurrence within the episomal system.
591 Promoters which exhibited a pronounced activity under
592 derepression conditions, like P_{ppALD4} , P_{ppFDH1} , P_{ppFLD1} , P_{HpFMD} ,
593 and P_{ppCAT1} (Figure 1 D), were present in 80% of all top
594 constructs. However, promoters with a strict methanol
595 dependent induction and low derepression, like P_{HpMOX} ,
596 $P_{ppPMP20}$, P_{ppDAS1} , P_{ppDAS2} , and P_{ppAOX1} , were the least often
597 occurring promoters.

598 Combining the insights of signal peptide and promoter
599 distributions revealed a multifaceted picture. Concerning
600 promoter distribution, the use of promoters with occurring
601 derepression profiles proved to be highly successful independent
602 of the attached protein. The signal peptide selection
603 proved to be less predictable, splitting the UPOs into two
604 groups. The long-type peroxygenase *Aae*UPO* was only
605 successfully secreted when attaching a signal peptide of a
606 long-type UPO (*Aae*-UPO* or *Gma*-UPO). The short-type
607 UPOs *Tte*UPO, *Mth*UPO, *Mfe*UPO, *Mhi*UPO, and *Dca*UPO
608 proved to be highly promiscuous toward a diverse set of signal
609 peptides with different lengths and sequences. On the basis of
610 these observations, the signal peptide suitability seems to be
611 more dependent on the attached protein if compared to the
612 respective promoter. The current number and the overall
613 knowledge of heterologously secreted UPOs is still very
614 limited.^{2,11} Hence, it is currently not possible to draw reliable
615 general conclusions that are valid for all UPOs.

616 Astonishingly, for all enzymes the top episomal and
617 integrative constructs contained orthologous promoter (6 \times
618 P_{HpFMD} ; 2 \times P_{HpMOX}), the integrative strains often being 2- to 3-
619 fold superior compared to the second or third best strains of
620 *P. pastoris* derived promoters (data not shown). Utilizing
621 P_{HpFMD} led to the lowest enzyme yields in the first test panel of
622 *Mth*UPO and *Tte*UPO (Figure 1 B and C), thereby further
623 emphasizing the importance of considering synergistic effects
624 of the promoter and the signal peptide choice. Solely the third
625 *H. polymorpha* derived promoter P_{HpDHAS} did not stand out;
626 however, it was found within an average episomal distribution
627 (6.3%)—more often than P_{HpMOX} (5%).

628 These observations confirm the high potential of ortholo-
629 gous *H. polymorpha* promoters and further prove their high
630 suitability on an episomal level. Utilizing these orthologous
631 promoters and without performing any optimization on
632 protein production of the diverse enzyme set, we were able
633 to achieve mg/L yields of all enzymes in shake flask format. In
634 most cases we could surpass previously reported yields of the
635 respective enzymes. There is still potential of reaching higher
636 volumetric yields after individual optimization of each protein
637 production setup. P_{HpFMD} proved to be an especially valuable
638 promoter not just resulting in high induced yields of up to 30
639 mg/L but being also active under methanol-free conditions
640 with 17 to 72% of the maximal yield achieved under induced
641 conditions. This feature renders methanol-free production a
642 feasible procedure addressing safety and health concerns.

643 Pleasingly, the designed two-layer system yielded good
644 results in both setups. It consists of an initial episomal
645 assembly and screening (layer 1) and subsequent transfer of
646 the entire expression unit to an integrative plasmid (layer 2).
647 This approach led to the discovery of highly active episomal as
648 well as integrative strains. Another scenario would have been
649 the selection of expression units, which are yielding an optimal
650 episomal production, but are less suitable as units for high-
651 yield protein production when integrated into the genome.
652 This hypothesis is also connected to the observed effect that
653 the set of repressed/strong induced promoter (P_{ppDAS1} ;
654 P_{ppDAS2} ; P_{ppAOX1}) is clearly underrepresented within the top-
655 performing episomal hits. However, if screening would have
656 been conducted solely using an integrative system, the
657 proportion of these promoters would have most likely
658 increased due to their generally high production rates when
659 used as integrative construct.⁴²

660 ■ CONCLUSION

661 The designed two-layer system of compatible episomal and
662 integrative plasmids enables the performance of a complete
663 enzyme engineering workflow in *P. pastoris*. Following the
664 identification of a suitable promoter/signal peptide combina-
665 tion and carbon source activity screening, the enzyme of choice
666 can be rapidly evolved within the episomal system—analogue
667 to directed evolution approaches in *S. cerevisiae*. Interesting
668 constructs or enzyme variants can be transferred directly to a
669 matching integrative vector for high yield antibiotic-free
670 protein production.

671 We are bridging a gap to previous UPO engineering and
672 directed evolution approaches in *P. pastoris* in general. This
673 gap was caused by the shortcoming of suitable episomal
674 expression plasmids offering high transformation efficiencies
675 and enzyme activities. This limitation was previously overcome
676 by a dual host approach, evolving the UPO in an episomal
677 *S. cerevisiae* system and subsequently transferring the evolved
678 mutant for high yield protein production to *P. pastoris*.¹⁴ To
679 highlight the versatility of the developed system, it was applied
680 to optimize the episomal yield of two other enzyme classes of
681 high interest: The lipase CalB and the laccase Mrl2. All
682 relevant plasmids are available at Addgene.

683 ■ MATERIALS AND METHODS

684 **Bacterial and Yeast Strains.** For all cloning purposes and
685 plasmid propagation *E. coli* DH10B cells (ThermoFisher-
686 Scientific, Waltham, US) were utilized. All work regarding
687 *Pichia pastoris* was performed utilizing the mut⁺ Strain X-33
688

688 (ThermoFisher Scientific, Waltham, US). All work regarding
689 *Hansenula polymorpha* was performed utilizing the wild type
690 strain Ha-1301 (DSMZ, Braunschweig, DE).

691 **Microtiter Plate Cultivation Expression of *P. pastoris***
692 **and *H. polymorpha*.** For enzyme production in microtiter
693 plate format specialized 96 half-deep well plates were utilized.
694 The model type CR1496c was purchased from EnzyScreen
695 (Heemstede, NL) and plates were covered with fitting
696 CR1396b Sandwich cover for cultivation. Plates and covers
697 were flushed before every experiment thoroughly with 70%
698 ethanol and air-dried under a sterile bench until usage. Each
699 cavity was filled with 220 μL of buffered complex medium
700 (BM) and inoculated with single, clearly separated yeast
701 colonies using sterile toothpicks. Basic BM (20 g/L peptone;
702 10 g/L yeast extract; 100 mM potassium phosphate buffer pH
703 6.0; 1 \times YNB (3.4 g/L yeast nitrogen base without amino acids;
704 100 g/L ammonium sulfate); 400 $\mu\text{g/L}$ biotin; 3.2 mM
705 magnesium sulfate; 25 mg/L chloramphenicol; 50 mg/L
706 hemoglobin; 150 mg/L Hygromycin B) was freshly prepared
707 out of sterile stock solutions immediately before each
708 experiment, mixed, and added to the cavities.

709 Depending on the type of experiment different carbon
710 source feeding strategies were employed. Therefore, defined
711 amounts (0.3%; 0.5%; 1.0% or 1.5% final) of the primary
712 carbon sources glucose and glycerol were added to the
713 cultivation media derived from defined stock solutions. Pure
714 methanol was added to a final concentration of 1.5 or 2% (v/
715 v). After inoculation of the wells the plates were covered,
716 mounted on CR1800 cover clamps (EnzyScreen) and
717 incubated in a Minitron shaking incubator (Infors, Bottmin-
718 gen, SUI) for 72 h (30 $^{\circ}\text{C}$; 230 rpm). After cultivation the cells
719 were separated from the enzyme containing supernatant by
720 centrifugation (3400 rpm; 50 min; 4 $^{\circ}\text{C}$).

721 **Peroxygenase Activity Measurement via NBD Assay.**
722 The use of 5-nitro-1,3-benzodioxole (NBD) as a suitable
723 microtiter plate substrate for the measurement of peroxygenase
724 catalyzed conversion to the colorimetric product 4-Nitro-
725 catechol has been described before.^{11,34} The described
726 conditions have been adapted with slight modifications. In
727 brief 20 or 40 μL of peroxygenase containing supernatant
728 (from 96 well plate setup) are transferred to a transparent
729 polypropylene 96 well screening plate (Greiner Bio-One,
730 Kremsmünster, AT) and 160 or 180 μL of screening solution
731 (final: 100 mM potassium phosphate pH 6.0; 1 mM NBD; 1
732 mM hydrogen peroxide; 12% (v/v) acetonitrile) added.
733 Absorption values (λ : 425 nm) of each well were immediately
734 measured after addition and brief shaking (3 s) in a kinetic
735 mode (measurement interval: 30 s) over a duration of 5 to 20
736 min utilizing the 96 well microtiter plate reader Spark 10 M
737 (TECAN, Grödig, AT). Slope values of absorption increase
738 corresponding to 4-nitrocatechol formation were obtained,
739 paying special attention to the linearity of the observed slope
740 to obtain reliable relative NBD conversion values for
741 comparison of the respective wells.

742 In the case of the initial screening of novel peroxygenases the
743 screening conditions were slightly modified. 40 μL of
744 supernatant were used and NBD as well as H_2O_2
745 concentrations reduced to 300 μM to prevent solubility issues.
746 4-Nitrocatechol formation was monitored as previously
747 described for 45 min.

748 **Peroxygenase Activity Measurement via DMP Assay.**
749 Rescreening setups of novel peroxygenases were performed
750 utilizing 2,6-dimethoxyphenol (DMP) as microtiter plate

substrate. The use of DMP as suitable substrate for the
measurement of peroxygenase catalyzed conversion to the
colorimetric product ceruginone has been described before.¹²
The described conditions have been adapted with slight
modifications. In brief, 40 μL of peroxygenase containing
supernatant (from 96 well plate setup) are transferred to a
transparent polypropylene 96 well screening plate (Greiner
Bio-One, Kremsmünster, AT) and 160 μL of screening
solution (final: 100 mM potassium phosphate pH 6.0; 3 mM
2,6-Dimethoxyphenol; 1 mM hydrogen peroxide) added.
Absorption values (λ : 469 nm) of each well were immediately
measured after addition in a kinetic mode (measurement
interval: 30 s) over a duration of 15 min utilizing the 96 well
microtiter plate reader Spark 10 M (TECAN, Grödig, AT).
Slope values of absorption increase corresponding to
ceruginone formation were obtained, paying special attention
to the linearity of the observed slope to obtain reliable relative
DMP conversion values for comparison of the respective wells.

CalB Lipase Activity Measurement via 4-Nitrophenyl

Laurate Conversion. 40 μL of lipase containing supernatant
were transferred to a transparent polypropylene 96 well
screening plate (Greiner Bio-One, Kremsmünster, AT) and
160 μL screening solution (final: 100 mM Tris-HCl pH 8.0; 1
mM 4-Nitrophenyl laurate; 1% (v/v) Triton X-100) added.
Absorption values (λ : 405 nm) of each well were immediately
measured after addition and brief shaking (3 s) in a kinetic
mode (measurement interval: 30 s) over a duration of 15 min
utilizing the 96 well microtiter plate reader Spark 10 M
(TECAN, Grödig, AT). Slope values of absorption increase
corresponding to 4-nitrophenolate release were obtained,
paying special attention to the linearity of the observed slope
to obtain reliable relative 4-nitrophenyl laurate conversion
values for comparison of the respective wells.

Mrl2 Laccase Activity Measurement Based on ABTS/ DMP Conversion.

Ten μL of laccase containing supernatant
were transferred to a transparent polypropylene 96 well
screening plate (Greiner Bio-One, Kremsmünster, AT) and
190 μL screening solution (final: 100 mM sodium citrate pH
4.0; 100 μM ABTS). Absorption values (λ : 418 nm) of each
well were immediately measured after addition and brief
shaking (3 s) in a kinetic mode (measurement interval: 30 s)
over a duration of 10 min utilizing the 96 well microtiter plate
reader Spark 10 M (TECAN, Grödig, AT). Slope values of
absorption increase corresponding to the formation of the
radical ABTS cation (ABTS $^{\bullet+}$) were obtained, paying special
attention to the linearity of the observed slope to obtain
reliable relative ABTS conversion values for comparison of the
respective wells.

Due to the rapid conversion of ABTS by Mrl2, later
screenings were performed using DMP as substrate to obtain
reliable slope values. Therefore, 10 μL of supernatant and 190
 μL of screening solution (final: 100 mM potassium phosphate
pH 6.0; 100 μM DMP) was utilized, and measurement was
performed as described above.

9. General Discussion and Perspective

Within this section the core results of this dissertation shall be briefly discussed, as the chapters already contain extensive discussion sections related to the respective publication. Therefore, the focus of this section is to summarise and connect the findings of this thesis in a comprehensive manner and assess the results regarding recent research findings that have been published in the fields of yeast secretion systems and UPO catalysis.

9.1 The construction of novel Golden Gate cloning circuits

The departure point of this dissertation has been the aim to build a novel mutagenesis system based on the principles of modular Golden Gate cloning^{217,218}, resulting in the construction of a fully integrated mutagenesis system coined Golden Mutagenesis²³¹. Inspired by the underlying Golden Gate principle of modularity and sequence guided overhang reassembly^{217,218}, we designed a system that exploits this programmable modularity for targeted mutagenesis of a gene template. Single examples of Golden Gate based systems for mutagenesis have been described before amongst others in the engineering of a lipase²³² and the creation of deletion and insertion libraries²³³. However, these examples were just amendable to the specific published system, lacking a fully integrated system that can be adapted by other researchers. To aid the widespread use of Golden Mutagenesis we have built a classical T7 promoter²³⁴ based plasmid for target protein production in *E. coli*, which further enables colour based on plate selection and deposited this plasmid at the non-profit plasmid repository Addgene (9 plasmid requests until 11th May 2021). The core feature of Golden Mutagenesis has been the successful implementation of a fully automated freely available online primer design tool (<https://msbi.ipb-halle.de/GoldenMutagenesisWeb/>), allowing the user to insert a specific gene sequence and retrieve the pivotal primer sequences for defined or single/multiple site saturation mutagenesis. Additionally, a graphical analysis tool for the distribution of nucleotides has been developed, displaying the achieved codon degeneracies at targeted residue positions based on the sequencing of a pooled, randomised plasmid library. This tool is based on previous reports coining this method “Quick quality control (QQC)”²³⁵. QQC is a pivotal factor to evaluate the successful construction of desired mutagenesis libraries which can sufficiently covering the complete created sequence space.

The successful implementation of Golden Mutagenesis is furthermore emphasised by the fact that all subsequent research work of this thesis either relied on the intrinsic modular logic of Golden Mutagenesis for episomal plasmid design and transcription unit assembly (chapter II and chapter VI) or the direct usage in directed evolution campaigns of peroxygenases (chapter III, chapter IV and chapter V).

Conserving the intrinsic design logic for the assembly of functional open reading frames in Golden Mutagenesis in subsequent work (chapter II and IV), we have expanded the species

range by providing novel episomal plasmids for target gene expression in the yeasts *Saccharomyces cerevisiae*²³⁶ and *Pichia pastoris*^{236,237}. We have constructed a versatile Golden Gate assembly kit (Yeast Secrete and Detect Kit) consisting of 42 unique plasmids which allows researchers to construct versatile target protein secretion libraries in both yeast species^{236,237}. To foster the use of the kit in the scientific community, this array of plasmids was also deposited at Addgene (4 requests until 11th May 2021). Besides the possibility of constructing signal peptide shuffling libraries (*S. cerevisiae* and *P. pastoris*) and combined promoter/signal peptide shuffling libraries (*P. pastoris*), we have further implemented the option for specific target protein detection in a high-throughput 96 well plate format.

The system is based the development of a split-GFP fluorescence assay²³⁸, dividing an engineered GFP variant (11 β -sheets) into a non-fluorescent GFP 1-10 fragment and a short GFP₁₁ fraction. This GFP₁₁ peptide can be used as small protein tag to label a target protein. Upon reassembly of both fragments, GFP fluorescence is restored and can be detected in a high-throughput manner using commercial fluorescence plate readers. We have included several C-terminal protein tags in the kit, which consists of a GFP₁₁ portion and additional peptide motifs for proteolytic cleavage and affinity based protein purification through a Hexa/Octa-Histidine²³⁹ or a Strep II protein tag²³⁹⁻²⁴¹. The split-GFP detection technology has recently been applied in the screening of enzyme variants in *E. coli* cell lysate^{242,243}, providing a powerful method to normalise enzyme activity within protein variant libraries by discriminating between activity improvement and increase in protein production/secretion. In the scope of this work, the developed split-GFP system proved to be a tremendous asset and will be further discussed in detail later. To the best of our knowledge, we thereby report the first utilisation of the split-GFP system in the directed evolution approaches using eukaryotic expression hosts.

9.2 Secretion optimisation through signal peptide shuffling

The initial idea of focusing on the development of a flexible signal peptide shuffling system, comprising 17 diverse signal peptides, has been derived from the core results of the directed evolution campaign of *AaeUPO** (PaDa-I)¹⁴⁹. Alcalde and co-workers were able to increase UPO secretion up to 8 mg/L¹⁴⁹ by introducing a total of nine amino acid exchanges to *AaeUPO*, four exchanges located within the natural signal peptide— hinting towards a crucial role of signal peptide composition for UPO secretion in the heterologous host *Saccharomyces cerevisiae*. The engineered signal peptide in combination with the wild type mature enzyme sequence led to a 27-fold increase of secretion, relative to the wild type gene¹⁴⁹.

To investigate this hypothesis, we built a peptide panel based on literature-reported signal peptides capable of guiding secretion in *S. cerevisiae*^{193,244-248} and further including described and predicted UPO derived signal peptides^{47,48,70,149}. Similar approaches of signal peptide library creation and subsequent screening of secretion libraries have been reported for

the secretion of different enzyme targets in the prokaryotic hosts *Bacillus subtilis*^{249,250}, *Corynebacterium glutamicum*^{251,252} and *Lactobacillus plantarum*²⁵³.

Selecting the previously engineered yeast secretion variant *AaeUPO** as test enzyme we constructed 17 different secretion constructs, comprising all individual signal peptides out of the Yeast Secrete and Detect panel²³⁶. Based on the C-terminal attachment of a GFP₁₁ detection tag^{238,242}, resulting UPO activity in the yeast supernatant could be directly correlated to the respective UPO secretion amount. Through signal peptide shuffling, we identified a signal peptide (*Gma-UPO*) derived from a putative long-type UPO, which increased *AaeUPO** activity and fluorescence read-out by 220% compared to the previously engineered signal peptide of *AaeUPO**. This effect was even more pronounced when utilising the same combination in the episomal *P. pastoris* system, exhibiting a 6-fold increase. These observations further emphasise the appeal and potential of the signal peptide shuffling approach. In general, the overall suitability of other signal peptides for *AaeUPO* production based on NBD activity measurements proved to be low, even though in many cases comparable split-GFP values were obtained. This indicates that comparable secretion levels, promoted by the respective signal peptides relative to the evolved signal peptide of *AaeUPO**¹⁴⁹, were achieved. This discrepancy points towards different signal peptide cleavage patterns, depending on the N-terminally attached signal peptide, resulting in differently processed UPO enzyme subtypes, exhibiting divergent enzymatic activities.

Utilising *Gma-UPO* as signal peptide, activity as well as split-GFP signal exhibited a uniform increase, indicating analogous peptide cleavage during maturation. This hypothesis was manifested through subsequent peptide analysis resolving the mature N-terminus (starting AEPGLPP), being in complete agreement with previous reports on *AaeUPO**^{149,150,168}, in contrast to the natural fungal enzyme where N-terminal proteolysis (EPG↓LPPPGPL) occurs³⁶.

By subsequent expansion of the signal shuffling system towards including nine wild type UPOs, a lipase and a laccase, we could acquire various interesting insights regarding the suitability of the constructed, divergent signal peptide panel for target protein secretion in *S. cerevisiae* as well as *P. pastoris*^{236,237}. A novel insight concerning the heterologous production of UPOs was the analysis of promiscuity of respective UPO subtypes towards suitable signal peptides for secretion.

As already discussed before, the long-type secretion variant *AaeUPO** seemingly exhibits low promiscuity towards the signal peptide subset, resulting in a pronounced activity loss when attaching most of the signal peptides²³⁶. This hypothesis was further strengthened in a subsequent simultaneous promoter and signal peptide shuffling approach performed in *P. pastoris*²³⁷. In this setup only 7 % of all clones exhibited UPO activity above the background threshold. Among the top 15 most active episomal constructs we exclusively identified either *Aae-UPO** or *Gma-UPO* as signal peptide. Recent results regarding the heterologous production

of two novel long-type UPOs derived from *Psathyrella aberdarensis*⁵⁰ (non-published results) in *Pichia pastoris* further support this hypothesis of overall low promiscuity of long-type UPOs towards the employed panel. Among the most active clones in case of both enzymes, we could exclusively identify the occurrence of the signal peptides derived from either *Cci*UPO, *Gma*UPO or *Aae*UPO*.

In contrast, when utilising short-type UPOs we observed medium (*Mfe*UPO: 24 %; *Dca*UPO: 26 %; *Mhi*UPO: 31 % active clones) and high promiscuity (*Mth*UPO: 56 %; *Tte*UPO: 66 % active clones). The comparably high promiscuity of short-type UPOs was moreover reflected by a highly divergent panel of occurring signal peptides among the respective top 15 episomal constructs of each enzyme²³⁷.

We could not obtain clear evidence for the superiority of certain signal peptides within the panel, but retrieved a rather broad distribution of all signal peptides among the 80 sequenced top constructs of 8 diverse enzymes²³⁷. The only exception being the previously mentioned low promiscuity of long-type peroxygenases, clearly favouring long-type UPO derived signal peptides for efficient secretion. Furthermore, we did not observe any pronounced species bias of signal peptide distribution between *S. cerevisiae* and *P. pastoris*, solely subtle differences in signal peptide preference for certain UPOs²³⁶. Interestingly, the signal peptides derived from *Mro*UPO and *Mth*UPO, which were previously never used to target protein secretion in a heterologous host, were found among the most overrepresented signal peptides. Both being also identified within the most suitable constructs for the episomal secretion of the unrelated lipase CalB (*Candida antartica*) and laccase Mrl2 (*Moniliophthora roreri*). Therefore, our initial utilisation and suitability verification of these UPO derived signal peptides might lead to future exploitations of UPO signal peptides for the secretion of other target proteins in yeast. Another interesting observation within this study has been the underrepresentation of the α factor prepro leader (*Sce*-Prepro), which has been used as “gold standard” signal peptide for secretion in both *S. cerevisiae* and *P. pastoris* in the last decades, also being a part of nearly all commercial plasmid systems for target protein secretion in both yeast organisms^{182,192,193,201}. In our setup, however, we obtained *Sce*-Prepro only among 3.8 % of all top constructs (average distribution: 5.9 %), whereas the signal peptides of *Mro*UPO and *Gma*UPO were found in 11.3 % of all cases, respectively.

In summary, in this thesis we have constructed a diverse, highly functional signal peptide panel for target protein secretion in the yeasts *Saccharomyces cerevisiae* and *Pichia pastoris*, aiming to test the hypothesis of increasing UPO secretion and aiding UPO identification through a simple diversification of secretion constructs. We were able to verify this hypothesis by the successful episomal production and secretion of nine wild type UPOs and further expansion of the shuffling concept towards other enzyme classes, thus bearing high potential for the secretion of other proteins of interest in future projects.

9.3 *Pichia pastoris* as directed evolution host

The methylotrophic yeast *Pichia pastoris* has been a heterologous host of outstanding industrial interest throughout recent decades, mainly due to a Crabtree-negative metabolism, high protein secretion capacities and a diverse set of strong methanol regulated promoters^{201,202,206}. In the field of directed evolution, however, the utilisation of *P. pastoris* has rarely been reported. Especially in comparison to *S. cerevisiae*, in which case a multitude of successful directed evolution campaigns, including peroxygenases^{149,169,172-174}, laccases^{158,254-258}, peroxidases^{259,260}, aryl alcohol oxidases^{61,159}, cellobiose dehydrogenase²⁶¹ and xylose isomerase²⁶², have been reported.

One reason for this shortcoming has been the rather tedious and ineffective DNA transfer through spheroplast generation and chemical transformation²⁶³. Later developments introduced optimised methods of cell preparation²⁶⁴ and electroporation²⁶⁵, thereby enabling sufficient efficiencies ranging from 10^4 to 10^6 transformants per μg linearised plasmid DNA for subsequent screening procedures. The second rationale has been the lack of suitable autonomously replicating sequences (ARS) for *P. pastoris*, which confer episomal stability as extrachromosomal elements and are commonly used features in expression plasmids of the standard heterologous production hosts *E. coli* and *S. cerevisiae*. In the case of *Pichia pastoris* on the contrary, nearly all production systems utilise genomically integrated expression cassettes, which can be used after an initial selection and identification step as stable production strains in bioreactor-setups, without the application of selective pressure through auxotrophy complementation or antibiotic selection^{201,203,204}.

First reports of ARS for the use in *Pichia pastoris* date back to 1985 introducing the endogenous PARS₁ and PARS₂ sequences²⁶³. The utilisation of PARS₁, the GAP promoter and the *Sce*-Prepro signal peptide led to the development of a first reported episomal plasmid design (pBGP₁) for directed evolution approaches in *Pichia pastoris*²⁶⁶. This plasmid backbone enabled a series of successful directed evolution campaigns evolving lipase A derived from *Candida antartica* towards diverse chemo- and enantioselectivities²⁶⁷⁻²⁷⁰, thus being the most prominent examples for classical directed evolution campaigns in *P. pastoris* to date. In 2014, a novel 432 bp ARS coined “panARS” derived from *Kluveromyces lactis* has been initially described constituting a broad species range, high transformation efficiency, and also conferring episomal stability in *P. pastoris*²⁷¹. Further studies characterising panARS determined an average copy number of 19 per cell^{272,273} and an overall superior stability and plasmid maintenance in comparison to PARS₁^{272,273}. When analysing the production of a fluorescent marker protein, either from a genomically single-integrated expression construct or an analogous panARS based episomal plasmid, episomal production resulted in substantial higher detectable protein amounts²⁷².

In this thesis we have successfully expanded the current plasmid portfolio for target gene expression in *P. pastoris* by implementing a novel series of episomal plasmids based on the

utilisation of the recently described panARS^{271,272}. Two episomal plasmids with fixed promoter module were constructed (pPAP001: P_{PpGAP} ²⁷⁴ and pPAP002: P_{PpCATi} ²⁰⁸), allowing for strong constitutive (P_{PpGAP}) or methanol-inducible gene expression (P_{PpCATi}). Both plasmids enable the execution of signal peptide shuffling approaches, resulting in 17 possible combinations for secretion as described in the previous section²³⁶. As a second system layer, we have built an integrative plasmid (pPAP003), in which the whole transcription unit of a suitable episomal plasmid can be swapped into. This plasmid is subsequently linearised and transformed to obtain stable yeast strains for large-scale protein production²³⁶. In a follow-up study, we have constructed a fourth plasmid lacking a fixed promoter (pPAP004), in which one out of a panel of eleven distinct MUT promoter can be inserted; amounting to 187 (11 x 17) possible combinations for secretion of a target protein if promoter and signal peptide shuffling are performed simultaneously²³⁷. By employing this episomal system, we were able to identify suitable episomal secretion constructs for eight UPOs (*AaeUPO**, *MthUPO*, *TteUPO*, *MhiUPO*, *MfeUPO*, *DcaUPO*, *MroUPO*, *CglUPO*) as well as lipase CalB and laccase Mrl2 and to further optimise the episomal production levels through carbon source screening²³⁷. Through transfer of beneficial expression constructs into pPAP003 we obtained stable high-producing strains for each enzyme.

We were able to support the insights of previous reports regarding panARS²⁷², as we could achieve higher UPO activities, when produced from episomal plasmids, than their very likely single-integrated genomic counterparts. Generally, we obtained an immense standard deviation within a pool of transformed integrative constructs of up to 80 %, which is caused by the occurrence of multiple genomic integration events, a commonly occurring feature of high-producing *P. pastoris* strains^{275,276}. Therefore, it is in our opinion not feasible to evolve an enzyme in an integrative system using the current setup, as its inherently high secretion variation substantially hampers the clear identification of improved enzyme variants in a directed evolution approach. With our designed system, we propose a dual approach of firstly evolving a protein within the episomal system (pPAP004 series) and then transfer the evolved protein to the integrative level (pPAP003) to access stable strains for subsequent upscaling and characterisation.

A similar approach of a modular secretion library has been reported by Sieber and co-workers before²¹⁰. Building upon parts and the logic of an existing *S. cerevisiae* Golden Gate system²²⁸, they provided a panel of 4 promoters as well as 10 signal peptides derivatives, all based on the *Sce*-Prepro signal peptide. While being a highly valuable resource and easily accessible through Addgene, the system bears some disadvantages. Genomic integration of the series is based on a Gateway recombination system and therefore solely applicable to one specially modified strain (*P. pastoris* NRRL Y-11430) and for episomal production it employs the less stable PARS1²¹⁰. Episomal and integrative level are furthermore not interconnected. All experimental

data have been collected using the naturally intracellular located fluorescent proteins eGFP and RFP, therefore missing clear indication for the suitability in the secretion of industrially relevant proteins.

9.4 Secretion optimisation through promoter shuffling

One key feature when using *P. pastoris* as heterologous production is the utilisation of strong methanol-regulated promoters, which are derived from genes involved in the highly specialised methanol utilisation pathway endogenous to methylotrophic yeasts²¹¹. The classically used strong promoter P_{PpAOX1} , P_{PpDAS1} and P_{PpDAS2} , also harnessed in nearly all commercial plasmid systems, exhibits tight repression in the presence of glucose and glycerol and strong induction upon addition of methanol^{201,208,277}. Based on this inherent sharp regulation profile, these promoters are highly attractive elements in large-scale setups, as during a fermentation the phases of biomass-accumulation (glycerol-feed) and target protein production (methanol-feed) can be precisely controlled²⁰¹. Later reports significantly increased the panel and knowledge about MUT promoters, also leading to the description of several promoters substantially active under derepressed conditions^{206,208}. Recently the panel of derepressed promoters has been further expanded by the introduction of orthologous MUT promoter for high-level protein production in *P. pastoris*^{213,214}.

In the scope of this thesis we have constructed two episomal plasmid series, namely two fixed promoter plasmids (pPAP001 and pPAP002)²³⁶, as well as a backbone plasmid (pPAP004) for the construction of versatile MUT promoter shuffling libraries²³⁷. In a first proof-of-concept study for episomal UPO production in *Pichia pastoris*, we employed either the strong constitutive P_{PpGAP} or the strong methanol-inducible P_{PpCAT1} . P_{PpCAT1} has been previously introduced as highly interesting novel MUT promoter, exhibiting pronounced derepression capacities, thereby outperforming the “gold-standard” P_{PpAOX1} in certain integrative expression setups^{208,278}. Within our initial episomal study we could obtain secretion of *AaeUPO**, *MthUPO* and *TteUPO* using both promoters to drive UPO expression, P_{PpCAT1} leading to slightly higher activities in nearly all cases. We subsequently compared UPO activity and split GFP intensities of *TteUPO* and *MthUPO* produced from the respective best-performing episomal constructs in *P. pastoris* and *S. cerevisiae*. The obtained results proved diminished activities stemming from the *P. pastoris* system, while being in an acceptable range of maximal activity (*MthUPO*: 60 % ; *TteUPO*: 40 %) ²³⁶. One striking observation within this study has been the combinatorial analysis of promoter and signal peptide interplay. When secreting *TteUPO* either with the *Sce-Prepro* or *Cci-UPO* signal peptide, using both promoters, striking effects were observed. Whereas in the case of P_{PpGAP} both signal peptides led to a comparable level of UPO secretion, for P_{PpCAT1} the utilisation of *Sce-Prepro* led to an approx. 20-fold higher UPO secretion level than *Cci-UPO*. These initial results point towards a strong synergistic effect of promoter strength and

signal peptide suitability for target protein secretion, rather than considering these factors in an isolated manner.

In a follow up study on episomal protein secretion in *P. pastoris*, we further analysed this hypothesis, broadened the scope of promoters by introduction of a MUT promoter shuffling module and introduced three further wild type UPOs into the modular system²³⁷. The eleven MUT promoters, eight originating from *P. pastoris* and three from *Hansenula polymorpha*, were chosen based on previous literature reports on endogenous^{208,208,209,278} and orthologous^{213,214} promoters. With the exception of P_{PpAOX1} ²¹⁰, none of these promoters have been utilised before within an episomal expression setup and the P_{HpDHAS} originating from *H. polymorpha* has not been described for target gene expression in *P. pastoris* at all. After functional verification of all promoter parts by using *Mth*UPO and *Tte*UPO as test set in combination with a suitable signal peptide for secretion, we further investigated the synergistic hypothesis stated before. We chose three promoters and six signal peptides, leading to 18 secretion constructs divided into six subgroups (grouped by signal peptide) for testing the UPO activity profiles within all groups. We could verify the hypothesis of synergistic effects of certain promoter signal peptide combinations, as we observed three divergent appearing patterns of UPO activity within the subgroups, which cannot be explained solely based on promoter strength and signal peptide suitability²³⁷. These insights point towards regulatory mechanisms during translation, protein folding, and glycosylation. A delicate balance, as desirable high protein rates of heterologous target proteins can readily overwhelm the cellular machinery, thus triggering target protein degradation by unfolded protein response²⁰².

Therefore, all subsequent approaches have been conducted as a combined promoter and signal peptide shuffling approach, assessing up to 187 unique combinations for secretion, aiming to balance off high functionality and secretion rates. Through application of this combined approach we could identify highly suitable episomal constructs for the secretion of six UPOs (*Mth*UPO, *Tte*UPO, *Aae*UPO*, *Mhi*UPO, *Mfe*UPO, *Dca*UPO) as well as the lipase CalB²⁷⁹ and the laccase Mrl2²⁸⁰.

Throughout the study we could obtain several valuable insights. Remarkably all best-performing episomal and integrative constructs of the eight diverse enzymes exhibited either the orthologous P_{HpFMD} (6x) or P_{HpMOX} (2x), thus being in complete agreement with recent results highlighting the outstanding potential of these two promoters^{213,214} for high-yield protein production in *Pichia pastoris*. Additionally, to these recent reports, we could confirm suitability on an episomal level and successfully introduce the third orthologous promoter (P_{HpDHAS}) for target gene expression. Utilising P_{HpFMD} for Mrl2 we achieved a 3-fold (31 mg/L) increase in volumetric yield, without performing any optimisation of the production setup and in comparison to the original report of Mrl2 production in *P. pastoris* utilising P_{PpAOX1} under optimised conditions (11 mg/L)²⁸⁰, thus further emphasising the high potential of P_{HpFMD} .

In contrast to the non-predictable and broad distribution of the signal peptides (see section 9.2), we could identify a clear rationale in the distribution of the eleven MUT promoters among the top 80 episomal expression constructs of the eight enzymes²³⁷. In 80 % of all top constructs, we identified promoter with pronounced activity under derepressed conditions (P_{HpFMD} , P_{PpFDH1} , P_{PpFLD1} , P_{PpALD4} , P_{PpCAT1}), whereas promoter with tight repression (P_{PpAOX1} , P_{PpDAS1} , P_{PpDAS2}) remained highly underrepresented among the top hits. Subsequent activity screening of various episomal constructs under different derepressed (0.5 to 1.5 % (v/v) glycerol) and co-feeding (0.5 to 1.5 % (v/v) glycerol; + 1.5 % (v/v) methanol) conditions revealed a highly diversified pattern, even when employing the same promoter (P_{HpFMD}). While in most cases (*MthUPO*, *TteUPO*, CalB, *Mrl2*) the highest activities were detected under co-feeding conditions, we also identified constructs (*AaeUPO**, *MfeUPO*), reaching the highest UPO activities under solely derepressed conditions without the addition of methanol. Combining these insights and considering the underrepresentation of classical strong, tightly-repressed promoters the previously stated synergism hypothesis can be further upheld. It seems plausible that promoters with a pronounced derepression are very suitable for episomal expression by exhibiting a more dynamic regulation range than tightly repressed promoter, thus being extremely valuable to balance off high protein secretion and cell proliferation/viability.

In summary, we have developed an extension of the previously implemented episomal shuffling system in *P. pastoris* (see section 9.2)²³⁶, allowing for combined shuffling approaches through the introduction of eleven MUT promoter modules. Suitable episomal secretion constructs can be identified within a high-throughput 96 well plate format and furthermore screened under various derepressed and co-feeding conditions to detect a certain “sweet spot” of maximal protein production. These “sweet spot” then displays a highly suitable departure point for subsequent directed evolution campaigns of any desired kind, employing the developed Golden Mutagenesis technique²³¹.

9.5 Expanding the panel of recombinant UPOs

At the beginning of this thesis in April 2017 the panel of recombinantly produced UPOs included solely two enzymes, namely *CciUPO* produced through a commercial *Aspergillus oryzae* strain⁷⁹ and a engineered *AaeUPO* variant evolved for increased secretion in *S. cerevisiae*¹⁴⁹. The *AaeUPO** variant, evolved in a classical directed evolution host, has been subsequently utilised as starting point for various campaigns, resulting in a multitude of specialised UPO variants^{169,172-174,176}. The ascomycetous mould *Aspergillus oryzae* on the contrary, has despite its great protein secretion capacities so far not been reported as directed evolution host, primarily due to the limitation of available plasmid systems, low-transformation efficiencies and long cultivation periods¹⁶⁷.

The extremely limited panel of recombinant UPOs has been considered the major bottleneck towards their widespread use in the field of biocatalysis in recent review articles^{52,100,117,148}. Closely linked to this small panel is the overall low amount of reported, highly specific UPO conversions, as nearly all published chemical data solely rely on the catalysed reactivities of the two wild type enzymes *AaeUPO* and *MroUPO*^{33,52}. Therefore, UPOs have recently been stated to be more enantio- than regioselective⁵².

In this thesis we succeeded in substantially expanding the panel of recombinantly produced UPOs. By implementing the signal peptide shuffling approach in *S. cerevisiae* and *P. pastoris*, we achieved the heterologous production of *MroUPO*⁴⁶, *CglUPO*⁴⁸, *MthUPO*²⁸¹ and *TteUPO*²⁸¹ as active wild type enzymes in both organisms²³⁶. Additionally, we were able to produce UPOs derived from *Marasmius wettsteinii*⁴⁷ (*MweUPO*) and *Galerina marginata*²⁸² (*GmaUPO*), however in both cases no active enzyme fractions could be obtained. In this regard the developed split-GFP assay proved to be an indispensable asset^{238,242}, as we could detect secretion of both enzymes in 20 µL of 96 well cultivation supernatant, even though classical colorimetric UPO substrates such as DMP¹⁶⁹ and NBD^{96,149} were not converted. The unequivocal occurrence of both proteins could be subsequently proven by protein digest followed by MS analysis²³⁶.

Interestingly, all first described wild type enzymes belong to the class of short-type UPOs, which seem to be easier producible in a heterologous yeast host. When testing the previously describe long-type enzyme *CciUPO*, we could not even detect a split-GFP fluorescence, thus pointing towards a complete lack of secretion, regardless of the attached signal peptide. The factor of low signal peptide promiscuity of long-type UPOs has already been discussed in detail (see section 9.2) before. To further investigate this factor, in another study we aimed for the construction of a chimeric long-type UPO gene libraries to be subsequently analysed regarding activity by a versatile GC-MS high-throughput approach²⁸³. Division and shuffling of five respective gene subunits of *AaeUPO*^{*}, *GmaUPO* and *CciUPO* led to the subsequent production and identification of six unique, active chimeric enzymes. This rather simple approach bears high potential to enhance genetic diversity substantially through straightforward gene shuffling methodologies and could further be performed randomly without using pre-defined genetic crossover points¹⁶⁶.

In the concluding chapter of this thesis, we achieved the first reported heterologous production of *DcaUPO*⁴⁹, *MfeUPO* and *MhiUPO* in *Pichia pastoris*²³⁷. Besides the possibility of assessing novel enzymes through the shuffling system, we also obtained the highest reported heterologous UPO yields within a shake flask setting to date, despite performing no optimisation of any respective production setups. By employing *P_{HpFMD}* for gene expression and *Gma-UPO* for secretion, we reached a volumetric titre of 12.6 mg/L for *AaeUPO*^{*}, thereby increasing the yield of 8 mg/L, which was previously reported within a comparable *P. pastoris* setup¹⁵⁹. An even more

pronounced effect could be obtained in case of the short-type enzyme *Dca*UPO, reaching a titre of 16.3 mg/L within our setup²³⁷, thus displaying an approximately 6-fold productivity increase in comparison to previous reports of production in *E. coli* (2.8 mg/L)⁴⁹. The initially described UPOs *Mth*UPO and *Tte*UPO proved to be highly suitable targets for secretion in both yeast organisms. Wild type *Tte*UPO could be readily secreted in *S. cerevisiae* up to a titre of 17 mg/L, thus being better secreted than the evolved secretion variant *Aae*UPO* (8 mg/L)¹⁴⁹. *Mth*UPO production proved to be exceptionally high in *P. pastoris*, reaching production titres of up to 24 mg/L²³⁶.

In addition to the overall high yields obtainable for all firstly produced peroxygenases (nine wild type and six chimeric enzymes), we could furthermore broaden the current reactivity spectrum of UPO catalysis²³⁶, thus addressing previous concerns about lacking UPO diversity and selectivity^{52,100,148}. Besides other shifted reactivities, especially the epoxidation of styrene is of interest, since it has been a rather unfavourable UPO substrate so far, as poor enantiomeric excesses of 2 % (*Aae*UPO*)²³⁶ and 7 % (*Aae*UPO)⁸⁴ have been reported. *Cgl*UPO exhibits an improved *ee* (44 %), while comparable product concentrations to *Aae*UPO* were obtained. Most strikingly, we achieved the stereoselective benzylic hydroxylation of a pharmaceutically relevant phenethylamine derivate by utilising *Cgl*UPO and *Mth*UPO– a substrate that cannot be converted by *Aae*UPO and *Mro*UPO²³⁶. Harnessing the high production titres of *Mth*UPO in *P. pastoris*, we transferred this highly interesting reaction to a preparative scale in a proof-of-principle study, resulting in the formation of 9.7 mg enantiopure alcohol product.

Meanwhile, Martínez and co-workers have reported in several studies on the first successful UPO production setups using the prokaryotic standard host *E. coli*. The three short-type enzymes *Mro*UPO^{151,177}, *Cvi*UPO^{49,147} and *Dca*UPO⁴⁹ were produced intracellularly as active enzymes, obtaining volumetric yields of 2.8 mg/L (*Dca*UPO) and 7.0 mg/L (*Cvi*UPO).

9.6 Directed evolution of wild type UPOs

Within this dissertation the development of Golden Mutagenesis²³¹, the implementation of the modular signal peptide shuffling system in *S. cerevisiae*²³⁶ and the discovery of novel wild type UPOs have laid the foundation for the execution of subsequent enzyme engineering projects. By harnessing the mutagenesis technique and using best performing episomal secretion construct in *S. cerevisiae*, two reports on the engineering of *Mth*UPO have been published (chapter IV and chapter V)²⁸⁴. These campaigns constitute the overall first reports of high-throughput directed evolution campaigns utilising a wild type UPO as point of departure.

Despite the initial production of three UPOs in the most widely utilised heterologous host *E. coli*, the obtained UPO yields are comparably low⁴⁹ when compared to the herein developed *P. pastoris* system^{236,237} (see section 9.5) and any indication of high-throughput capacity is missing so far^{49,147,151}. Nevertheless, various mono- and di-substituted variants could

be obtained by targeted mutagenesis, produced and analysed for altered reactivities^{49,147,151}. In case of *Mro*UPO, through introduction of two phenylalanine residues (I153F, S156F), epoxidation of oleic acid was abolished¹⁵¹, whereas the epoxidation of α -linolenic acid was strongly favoured¹⁷⁷, thus mimicking the natural reactivity of *Aae*UPO¹⁷⁷. For *Cvi*UPO, two substituted heme channel variants (F88L and T158F) were assessed, exhibiting differential product distributions of epoxidation versus hydroxylation products when choosing oleic acid, linoleic and α -linolenic acid as respective unsaturated substrates¹⁴⁷.

In this thesis (chapter IV) *Mth*UPO was evolved towards the conversion of the classical colorimetric UPO substrate NBD^{96,149}, assessing approximately 5300 primary transformants of single and double-site saturation mutagenesis libraries, as well as recombination libraries of prior identified beneficial mutations²⁸⁴. Throughout the campaign the catalytic efficiency of NBD conversion could be increased 16-fold, spanning a range from 1.9×10^4 for the wild type up to 3.1×10^5 ($M^{-1} s^{-1}$) for the best performing variant L60F/S159G/A161F²⁸⁴. This variant therefore reaches nearly half the catalytic efficiency of *Aae*UPO* ($7.0 \times 10^5 M^{-1} s^{-1}$)¹⁴⁹, which is a highly suitable catalyst for the conversion of the aromatic substrate NBD due to a heme access channel predominantly shaped by phenylalanine residues^{36,168,175}. This hypothesis is further supported by the observation that two out of the three introduced amino acid exchanges within the active site of *Mth*UPO are phenylalanine residues. Strikingly, when testing the conversion of 2-methylnaphthalene with different variants, three divergent product selectivities could be obtained, leading to the predominant formation of 6-methyl-1,4-naphthoquinone (wild type *Mth*UPO), 2-methyl-1,4-naphthoquinone (variant L60F/S159G/A161F) and 2-naphthylmethanol (variant L60F)²⁸⁴. This observation further underlines the immense appeal and potential of directed evolution as methodology to address suboptimal selectivities accessible through the current, limited panel of recombinant UPOs^{52,100,148}. Once again, the developed split-GFP assay^{236,238,242} provided valuable insights throughout the campaigns, as it enabled to access the created site-saturation libraries for UPO enzyme secretion and identify potential deleterious effects of certain mutagenesis sites, causing an abolished secretion of resulting variants.

In a second project²⁸⁵ (chapter V) the previously created single-site saturation libraries of nine *Mth*UPO active site residues were further analysed, thus not following a classical directed evolution of consecutive mutagenesis and screening, but rather a reaction profiling approach. Harnessing a further enhanced version of the previously introduced MISER methodology²⁸³, approximately 900 transformants (from 9 libraries) were analysed for the conversion of the substrates octane, cyclohexane and cyclohexene. Enzymatic conversions were performed in a one-pot reaction setup and subsequently analysed towards the formation of up to six distinct products. In this study, especially UPO variant A161L proved to be of enormous interest. When employing this enzyme variant, a significant formation of 1-octanol (38 % of total products) could be obtained, a reaction product not accessible when utilising the wild type enzyme.

Furthermore, this variant enabled slightly higher substrate conversion (+ 12 % to wild type) and substantially improved stereoselectivity of epoxidation (75 % *ee* vs. 17 %) in the conversion of the substituted alkene substrate, 1-methyl-1-cyclohexene.

9.7 Future directions

The results of this thesis lay a foundation to pursue a broad range of future directions to contribute to the understanding and application of fungal peroxygenases. Based on the first high-yield production of *Mth*UPO and *Tte*UPO in *P. pastoris*, it would be of outstanding interest to obtain crystal structures of both enzymes. So far only three crystal structures of UPOs have been reported, namely for *Aae*UPO³⁶, the yeast secretion variant *Aae*UPO*¹⁶⁸ and *Mro*UPO (unpublished report), thus severely impeding the structural understanding of substrate preferences and resulting chemo/stereoselectivities of respective enzymes. Recent years have witnessed the advent of sophisticated technologies for computational enzyme design and modification^{286,287}, enabling the identification and targeting of critical residues to tailor enzymatic properties. However, these designs severely rely on detailed structural information of the respective enzyme, in nearly all cases obtained through protein crystallography²⁸⁸. Moreover, *Tte*UPO and *Mth*UPO only possess a modest sequence identity of respectively 31 % towards the available structure of *Mro*UPO, thus most likely crystal structures of the enzymes would provide valuable new insights into this new branch of short-type UPOs.

Another emerging topic amendable to UPO catalysis has been the resurrection of ancestral enzymes²⁸⁹. In this approach, amino acid sequences of modern enzymes retrieved from genomic sequence data are utilised and compared to calculate hypothetical common ancestors based on phylogenetic grouping and analysis²⁸⁹. These retrieved and resurrected ancestral enzymes often exhibit improved parameters regarding enzyme stability and substrate promiscuity²⁹⁰⁻²⁹². Regarding UPOs, highly application-oriented factors would include the improvement of the sensitivity towards hydrogen peroxide¹¹⁶, increased solvent stability^{172,173} and substrate loading.

Resurrected UPOs would be furthermore of high interest for an implementation within chemo-enzymatic workflows. In recent years, several engineered oxidoreductases have been successfully implemented into workflows combining classical organic chemistry and biocatalysis to access hydroxylated or epoxidized high-value compounds, often catalysing a final installation of outstanding stereo- and regioselectivity, commonly referred to as “late-stage functionalisation”²⁹³⁻²⁹⁵. Within this thesis, we achieved a proof-of-principle application of *Cgl*UPO and *Mth*UPO for the synthesis of an pharmaceutically relevant enantiopure phenethylamine alcohol product up to a preparative scale (for *Mth*UPO), which is amenable for further diverse amine functionalisation chemistry²³⁶. This promising result can be further exploited by employing ancestral UPOs, which are resurrected based on the sequence of

*Mth*UPO, potentially exhibiting beneficial process parameter such as higher process stability and substrate loading, while conserving the obtained, outstanding stereoselectivity of hydroxylation (*ee* > 98 %). So far, UPO catalysis has relatively rarely been reported on a preparative product scale²⁹³. Reports include the hydroxylation of ethylbenzene¹⁰², propranolol¹⁷⁴, testosterone⁴⁸ and the epoxidation of naphthalene⁵⁴ and α -linoleic acid¹⁷⁷. Further implementations of UPOs into preparative scale synthetic routes are of outstanding magnitude, as these reports would set a crucial benchmark for moving peroxygenases into a farther application-oriented direction^{52,148,293}.

Besides the discovery and engineering of novel UPOs the second major goal of this thesis has been the development of modular yeast-based systems for target protein secretion^{236,237}. Application of the implemented system resulted in the so far highest reported recombinant shake flask yields for *Aae*UPO*, *Mth*UPO, *Tte*UPO and *Dca*UPO^{236,237}. The modular system also offers multiple viable departure points for subsequent studies. Regarding UPOs, it would be of high interest to transfer the identified secretion constructs to a fermentation setup to exploit the full potential of *P. pastoris* as heterologous secretion host^{201,203,204}. To date, the highest recombinant peroxygenase yields of 217 mg/L have been reported for *Aae*UPO* utilising *P. pastoris* within a fermentation setup¹⁵⁰. Especially based on the outstanding potential of *P_{HpFMD}* indicated before²³³ and further manifested herein²³⁷, it seems reasonable that the identified constructs are capable of surpassing the volumetric UPO yields reported for *Aae*UPO*¹⁵⁰. Favourable starting points are *Tte*UPO and *Mth*UPO, since already more than 20 mg/L recombinant UPO were obtained in simple, non-optimised shake flask production setups^{236,237}. Reaching a g/L titre of recombinant enzyme production constitutes another important benchmark for the broader applicability of UPOs by supplying an adequate amount of catalyst for subsequent reaction upscaling. Additionally, high yields are beneficial for subsequent UPO crystallisation trials as mentioned before.

The modular *P. pastoris* system itself could be easily expanded by introducing novel genetic parts, since novel signal peptides for secretion^{296,297} and promoter parts^{298,299} are constantly being discovered. The utilised panARS^{271,272}, confers episomal stability in *P. pastoris* amongst several other yeast species, but has so far not been substantially optimised for ideal performance in this host. Therefore, future campaigns evolving this sequence by means of directed evolution could further increase plasmid maintenance and stability, as well as episomal protein production in *P. pastoris*. A principle of high relevance and broad applicability for heterologous target gene expression, which has previously been reported for tailored gene expression in multiple prokaryotic organisms³⁰⁰⁻³⁰². As a concluding result of this thesis, we obtained a proof of general functionality of the designed pPAPoo4 plasmid series in *H. polymorpha*, which is besides *P. pastoris* the second methylotrophic yeast host of outstanding industrial interest^{303,304}. Subsequent studies could aim to expand the system and introduce *H.*

polymorpha as novel high-throughput amendable directed evolution yeast host besides *Saccharomyces cerevisiae* and *Pichia pastoris*.

Another major bottleneck of UPO catalysis constitutes the extremely limited panel of reactivities, combining high stereo- and regioselectivity⁵². So far only three reactivities of *Aae*UPO that fulfil these criteria have been described, namely the stereoselective hydroxylation of ethylbenzene, tetrahydronaphthalene and the epoxidation of cis- β -methyl styrene⁷⁹. The introduction of thirteen novel, active wild type or chimeric peroxygenases within this thesis offers a tremendous potential to broaden the current landscape of UPO catalysis towards novel highly selective transformations as well as the conversion of new substrates. This potential was assessed and emphasised through the testing and comparison of *Cgl*UPO, *Mth*UPO and *Tte*UPO as new enzyme set within this thesis, as substantially divergent patterns of stereoselectivity for the epoxidation of styrene as well as for benzylic hydroxylation activity of a homologous row of phenyl alkanes were obtained²³⁶. The remaining outstanding potential of this enzyme pool can be efficiently assessed in future projects by implementing the developed versatile GC-MS high-throughput MISER²⁸³ methodology and its expansion²⁸⁵. Fasan and co-workers have reported a similar, successful approach for broadening the scope of selective (sesqui)terpene hydroxylation catalysed by various CYPs in a process coined “fingerprinting”^{305,306}.

Two initial examples of the directed evolution of wild type UPOs were reported in this dissertation thesis^{284,285}. Additional directed evolution endeavours can be executed by employing either classical colorimetric assays^{96,149,169} or the developed versatile GC-MS methodology^{284,285}. One interesting departure point for future campaigns is the identified *Mth*UPO variant A161L, which forms 38 % of 1-octanol as product upon octane conversion and could be further evolved towards selective terminal hydroxylation. Terminal hydroxylation of non-activated alkanes displays a highly challenging reaction, as this position is the least favoured position for hydroxylation due to poor hyperconjugation³⁰⁷. Arnold and co-workers reported on the engineering of CYP BM₃ for specific subterminal³⁰⁸ and enriched (58 % selectivity) terminal hydroxylation³⁰⁹ of octane. Colorimetric surrogate substrates for rapid screening of terminal hydroxylation include the use hexyl methyl ether for subsequent aldehyde detection via the Purpald-Assay³⁰⁹ and p-nitrophenyl substituted alkanes³¹⁰, both reactions proceeding through the formation and subsequent decay of instable hemiacetals species.

10. Authorship Declaration

Chapter I:

Golden Mutagenesis: An efficient multi-site-saturation mutagenesis approach by Golden Gate cloning with automated primer design

by: **Pascal Püllmann**^{*}, Chris Ulpinnis^{*}, Sylvestre Marillonnet, Ramona Gruetzner, Steffen Neumann & Martin J. Weissenborn

^{*}shared first authorship

in: *Scientific Reports* **9**, 10932 (2019); doi: 10.1038/s41598-019-47376-1

Estimated overall contribution: 50 %

Specific tasks: Design and experimental planning of the research project (with MJW); design and construction of the Golden Gate system (with SM); execution and analysis of most experimental data (supported by RG); conceptual and supportive work for the implementation of the primer design tool; writing of the manuscript (with MJW)

Chapter II:

A modular two yeast species secretion system for the production and preparative application of unspecific peroxygenases

by: **Pascal Püllmann**, Anja Knorrscheidt, Judith Münch, Paul R. Palme, Wolfgang Hoehenwarter, Sylvestre Marillonnet, Miguel Alcalde, Bernhard Westermann & Martin J. Weissenborn

in: *Communications Biology* **4**, 562 (2021); doi: 10.1038/s42003-021-02076-3

Estimated overall contribution: 70 %

Specific tasks: conception and design of the research project (with MJW); design and implementation of the modular two yeast Golden Gate system (with SM); gathering and analysis of approx. 80 % of experimental data (further contributions by AK, JM, PRP and WH); coordination of the project (with MJW); deposition of plasmids with Addgene; writing of the manuscript (with MJW)

Chapter III:

Identification of Novel Unspecific Peroxygenase Chimeras and Unusual YfeX Axial Heme Ligand by a Versatile High-Throughput GC-MS Approach

by: Anja Knorrscheidt, **Pascal Püllmann**, Eugen Schell, Dominik Homann, Erik Freier & Martin J. Weissenborn

in: *ChemCatChem* **12**, 4788 (2020). doi: 10.1002/cctc.202000618

Estimated overall contribution: 25 %

Specific tasks: design and construction of the UPO chimeric gene libraries; primary screening and identification of chimeric UPOs for subsequent GC-MS screening; development of the *E. coli* mutagenesis system; supportive part in writing of the manuscript (mainly by AK and MJW)

Chapter IV:

Accessing Chemo- and Regioselective Benzylic and Aromatic Oxidations by Protein Engineering of an Unspecific Peroxygenase

by: Anja Knorrscheidt, Jordi Soler, Nicole Hünecke, **Pascal Püllmann**, Marc Garcia-Borràs & Martin J. Weissenborn

in: *ACS Catalysis*; under revision

Estimated overall contribution: 15 %

Specific tasks: discovery and first characterisation of the utilised target enzyme (*MthUPO*); design and method development for mutagenesis, cell cultivation, protein production and - purification; measurement of thermostability values

Chapter V:

Simultaneous Screening of Multiple Substrates with an Unspecific Peroxygenase Enabled Modified Alkane and Alkene Oxyfunctionalisations

by: Anja Knorrscheidt, Jordi Soler, Nicole Hünecke, **Pascal Püllmann**, Marc Garcia-Borràs & Martin J. Weissenborn

in: *Catalysis Science and Technology* (2021); doi: 10.1039/DoCY02457K

Estimated overall contribution: 15 %

Specific tasks: discovery and first characterisation of the utilised target enzyme (*MthUPO*); supplying seven recombinant UPOs for reactivity screening; design and method development for mutagenesis, cell cultivation, protein production and - purification

Chapter VI:

Improving the Heterologous Production of Fungal Peroxygenases through an Episomal *Pichia pastoris* Promoter and Signal Peptide Shuffling System

by: **Pascal Püllmann** & Martin J. Weissenborn

in: *ACS Synthetic Biology* (2021); doi: 10.1021/acssynbio.0c00641

Estimated overall contribution: 90%

Specific tasks: conception and design of the research project; design and implementation of the modular Golden Gate promoter shuffling system; planning, execution and analysis of experimental data; deposition of plasmids with Addgene; writing of the manuscript (with MJW)

Affirmative Statement of the Supervisor

The above described contributions of Pascal Püllmann are correct and the estimated contributions to the six publications are appropriate.

Jun.-Prof. Dr. Martin J. Weissenborn

Supervisor and thesis editor

Ihr Antrag auf Gewährung eines Stipendiums nach dem Graduiertenförderungsgesetz (GVBl. LSA 2001, S. 318) des Landes Sachsen-Anhalt, zuletzt geändert durch das Vierte Gesetz zur Änderung des Landesgraduiertenförderungsgesetzes (GVBl. LSA 2015, S. 613)		
Sehr geehrter Herr Püllmann,		
ich freue mich, Ihnen mitteilen zu können, dass die Graduiertenförderungskommission der Martin-Luther-Universität Ihnen ein Stipendium nach dem Graduiertenförderungsgesetz des Landes Sachsen-Anhalt dem Grund nach für die Zeit vom		
01.04.2017 – 31.03.2020		
bewilligt hat.		
Die Bewilligung des Stipendiums erfolgt unter folgenden Maßgaben:		
<ol style="list-style-type: none">1. Das Stipendium wird zunächst für einen Zeitraum von zwei Jahren, d.h. vom 01.04.2017-31.03.2019, gewährt. Sie erhalten ein monatliches Stipendium in Höhe von 1.100 Euro. Auf § 7a Graduiertenförderungsverordnung wird hingewiesen.2. Sie sind gemäß § 9 Absatz 1 Graduiertenförderungsgesetz verpflichtet, im Abstand von jeweils sechs Monaten über den Stand Ihres Vorhabens zu berichten. Ihren Bericht lassen Sie mir bitte über Ihren Betreuer bzw. Ihre Betreuerin, der bzw. die dazu eine Stellungnahme abgeben muss, zukommen. Auf § 9 Abs. 2 Graduiertenförderungsgesetz wird hingewiesen.3. Die weitere Bewilligung des Stipendiums im dritten Jahr, d.h. vom 01.04.2019-31.03.2020, setzt gemäß § 3 Absatz 2 und 3 Graduiertenförderungsverordnung voraus, dass Sie mit Ablauf des zweijährigen Förderzeitraums einen ausführlichen Arbeitsbericht vorlegen und Ihr Betreuer bzw. Ihre Betreuerin dazu eine ausführliche positive Stellungnahme abgibt. Zur Vorlage der Unterlagen erhalten Sie rechtzeitig eine schriftliche Aufforderung.		
Mit dem Erhalt des Stipendiums verpflichten Sie sich, die im Graduiertenförderungsgesetz und in der Graduiertenförderungsverordnung genannten Bedingungen einzuhalten. Insbesondere sind die Abgabetermine der Zwischenberichte und des Abschlussberichtes zu beachten.

Zwischenbericht über den Stand des Dissertationsvorhabens

Sehr geehrter Herr Püllmann,

für die Vorlage Ihres Zwischenberichtes zum gegenwärtigen Stand Ihres Forschungsvorhabens bedanke ich mich.

Die Graduiertenförderungskommission der Martin-Luther-Universität hat in ihrer Sitzung am 06. März 2019 nach Prüfung der eingereichten Unterlagen festgestellt, dass sich Ihr Vorhaben in einem erforderlichen Maß entwickelt hat. Einer Weiterbewilligung Ihrer Förderung bis zum 31.03.2020 steht somit gegenwärtig nichts im Wege.

Für Ihre weitere Arbeit wünsche ich Ihnen viel Erfolg und verbleibe mit freundlichen Grüßen
im Auftrag
